ABSTRACT

In this paper we experimentally study the impact of one EDCA parameter, namely *AIFSN* on a mixed voice/data wireless transmission. In particular we investigate how the tuning of this parameter affects both the voice transmission quality and background data throughput. We predict end-to-end voice transmission quality from time varying transmission impairments using the latest Appendix to the ITU-T E-model. Our experimental results show that the tuning of the *AIFSN* parameter can successfully prioritize voice transmission over data in a real 802.11e network. To the best of our knowledge, this is the first experimental investigation on tuning of MAC layer parameters in a real 802.11e WLAN network and its effect on end-to-end voice transmission quality.

Index Terms — speech communication, data transmission, wireless LAN, voice transmission quality, IEEE802.11e WLAN.

1. INTRODUCTION

Real-time voice transmission over wireless LAN (VoWLAN) imposes stringent requirements on transmission impairments such as end-to-end delays, jitter, and packet loss. The responsibility of meeting these requirements is shared between the various communication layers. Actions at the application layer include efficient encoding and packetization schemes, packet loss concealment (PLC) techniques, adaptive de-jitter buffering, echo cancellation, etc. On the network side, the new IEEE 802.11e protocol supports voice traffic by differentiating channel access probability among different traffic categories. In particular, the new, extended channel access mechanism (EDCA) allows for adjusting a number of channel access parameters at the L2/MAC layer to prioritize VoIP packets over other traffic types.

Application-layer adaptation mechanisms and MAC-layer parameters tuning can greatly mitigate the effect of transmission impairments and thus improve speech transmission quality. However, these mechanisms are often complex and difficult to tune properly. We claim that if a part of the VoIP transmission path is being tuned, the impact of local tuning actions on the whole end-to-end

(mouth-to-ear) transmission has to be taken into account. For this reason we developed a method for evaluating user satisfaction regarding end-to-end VoIP transmission quality from time varying transmission impairments. This method has shown to be particularly effective in evaluating various playout buffer algorithms [1, 2], assessing VoIP performance in Voice over WLAN systems [3, 4, 5], and was recently standardized by the ITU-T [6] as an Appendix to [7].

In this paper we use this method to experimentally evaluate the capability of the EDCA mechanism to support voice traffic in a mixed voice/data transmission over 802.11e WLAN. We investigate how real-time voice can be supported by tuning one EDCA parameter, namely *AIFSN* and how this impacts background data transmission. This paper is structured as follows. In Section 2, the 802.11e WLAN experimental setup is described, EDCA mechanism is outlined and proper de-jitter buffering at application layer is addressed. Experimental results are presented and discussed in Section 3. Finally, the paper is concluded in Section 4.

2. 802.11E WLAN EXPERIMENT

2.1. Experimental testbed.

The 802.11e wireless/wired test bed consists of 15 desktop PCs acting as wireless VoIP terminals, one desktop PC acting as a background traffic generator, and one desktop PC acting as an access point (AP). All machines in the test bed use 802.11 PCMCIA wireless cards based on Atheros chipsets controlled by MadWiFi wireless drivers and Linux OS (kernel 2.6.9). The MadWiFi drivers (Release 0.9.1 and above) provide working implementation of IEEE 802.11e EDCA mechanism [8]. All of the nodes are also equipped with a 100Mbps Ethernet cards. The PC that acts as access point routes traffic between the wired network and the wireless clients, and vice versa (each PC has two interfaces: one on the wireless and one on wired network). During the experiments each VoIP terminal runs one VoIP session and all sessions are bi-directional. In this way each terminal acts as the source of an uplink flow (i.e. sender) and the sink (i.e. receiver) of a downlink for a VoIP session. The wired interface off one PC is used to generate background traffic which is routed via the AP to

the wireless interface of the same PC. All generated traffic involved a wired and a wireless interface so that no traffic was generated between wireless interfaces. The wireless stations were located within 5 meters range from the AP to ensure that the wireless link quality is good. This test bed is illustrated in Fig. 1. Voice traffic was generated using RTPtools [9] which generated G.711 encoded voice packets (80bytes audio frames created every 10ms) with fixed IP packet overhead of 12bytes for RTP, 8bytes for UDP, and 20bytes for IP layer.

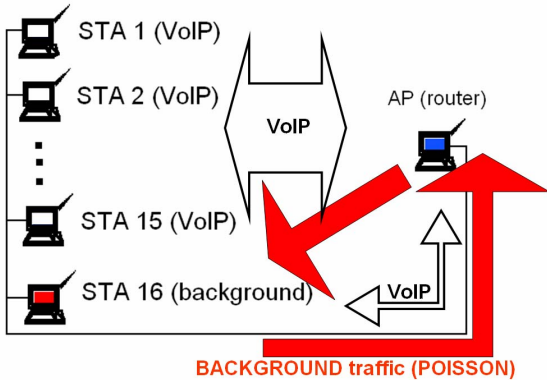

Figure 1. Experimental 802.11e test bed

During the experiments bi-directional transmission of packets was realized in the form of alternating active and passive periods modeled as a four state Markov chain (talker A active, talker B active, both active, both silent). The duration of states and the transitions between them followed the ITU-T recommendation P.59. [10]. This resulted in an ON-OFF modulated CBR traffic stream being generated. Background traffic in the form of Poisson distributed UDP packet flow was generated using MGEN traffic generator [11]. For the experiments we used 1, 2, and 4Mbps background traffic. To measure effective throughput (goodput) of the background traffic we used TRPR package [12]. The size and sending rate of the IP packets comprising the load is specified in Table 1.

Table 1. The size and sending rate of the packets comprising the background load

| IP packet size [Bytes] | 1Mbps load [pps] | 2Mbps load [pps] | 4Mbps load [pps] |
|------------------------|------------------|------------------|------------------|
| 256 | 488 | 977 | 1954 |
| 512 | 244 | 488 | 977 |
| 1024 | 122 | 244 | 488 |
| 1500 | 83 | 167 | 336 |

The reasoning behind choosing UDP and not TCP as a transport protocol for carrying background traffic is threefold: 1) UDP background traffic gives more accurate estimate of the actual load in the network (no retransmissions at transport layer) 2) results obtained with UDP constitute an upper bound for the throughput possible with TCP; 3) retransmissions of lost or corrupted packets is done by the 802.11 MAC-layer so TCP do not get affected by the packet loss [13].

During experiments all the measured VoIP data (packet arrival times, timestamps, sequence numbers, and marker bits) was collected at all receiving terminals to be processed later (off-line) by a program that simulated the behavior of the de-jittering buffer. Finally, the quality assessment algorithm was used to predict the quality of voice transmission.

2.2. MAC-layer parameters tuning

The newer IEEE standard 802.11e offers two modes of MAC operation: contention-based channel access called Enhanced Distribution Coordinate Access (EDCA) and contention-free channel access called Hybrid Controlled Channel Access (HCCA). In our experiments we have focused on the performance of the EDCA mode that differentiates the channel access probability among different traffic categories (TCs). When this operational mode is used, the packets are categorized in different TCs, and later mapped to four prioritized output queues called access categories (ACs). Each AC uses a set of parameters that controls the access probability to the wireless medium:

- *AIFSN* parameter controls the idle time (i.e. the the arbitration interframe space, AIFS) after which a transmission may occur;
- *CWmin* and *CWmax* parameters define the range of the contention window (CW) values from which the back-off time is randomly selected;
- *TXOP* parameter controls the time interval for which a station holds the channel (transmission opportunity) allowing for multiple packet transmission on a single channel access opportunity.

Configuring these parameters for each AC separately enables access probability differentiation between TCs. Since a station with packet to send must wait until the medium is idle and then wait for an additional period of time AIFS, the *AIFSN* parameter for the voice AC_VO ($AIFSN_{AC_VO}$) should be smaller than the *AIFSN* parameter for the background AC_BK ($AIFSN_{AC_BK}$). In this way time-sensitive voice traffic will contend sooner for accessing the wireless medium and thus will on average more transmission opportunities over the less-sensitive background traffic. After the AIFS period, the stations with a packet to send select random numbers between the *CWmin* and *CWmax* for each contending AC. Since the smallest number indicates “the winner”, the values of *CWmin* and *CWmax* should be lower for the voice queue than for the background queue. In general the combination of *AIFSN*, *CWmin* and *CWmax* should be configured so that high-priority voice packets win transmission opportunities over background traffic. However, to avoid situations in which the low-priority traffic is completely blocked, the sum of *AIFSN* plus *CWmax* for high-priority voice should be greater than *AIFSN* for low-priority traffic. In our experiments the voice packets were mapped into the voice AC (AC_VO) queue while the data traffic was mapped into the

background (AC_BK) queue based on their TOS values in IP packets' headers.

During the experiment we prioritized voice over background traffic by increasing the number of time slots comprising the background AIFS period ($AIFSN_{[AC_BK]}$) from 2 to 15 slots. All the other AC_BK parameters were: $CW_{min}=7$, $CW_{max}=1023$, $TXOP=0$ and they were kept fixed for the duration of the first experiment. The parameters under consideration for both AC_BK and AC_VO are listed in Table II

Table 2. EDCA parameters settings during the experiments

| Access Parameter | AC_VO (STAs and AP) | AC_BK (STAs and AP) |
|------------------|---------------------|---------------------|
| CW_{min} | 7 | 7 |
| CW_{max} | 1023 | 1023 |
| $AIFSN$ | 2 | 2,3,...14,15 |
| $TXOP$ | 0 | 0 |

2.3. Application-layer parameters tuning

In our experiments we used Ramjee's algorithm [14] which is often used as a reference playout buffer controller. The algorithm uses the same playout delay throughout a given talkspurt but permits different playout delays for different talkspurts. We modified the original Ramjee's algorithm by adding one parameter, namely *playout_offset* that represents additional pre-buffering delay. In our solution the playout time p_i at which the i -th packet, assumed to be the first packet in a talkspurt (played at the destination) is calculated as follow:

$$p_i = t_i + \hat{d}_i + \beta \cdot \hat{v}_i + \text{playout_offset} \quad (1)$$

where \hat{d}_i and \hat{v}_i are the estimates of delay of the i -th packet delay n_i and its variance respectively and are calculated as follows:

$$\hat{d}_i = \alpha \cdot \hat{d}_{i-1} + (1 - \alpha) \cdot n_i \quad (2)$$

$$\hat{v}_i = \alpha \cdot \hat{v}_{i-1} + (1 - \alpha) \cdot |\hat{d}_i - n_i| \quad (3)$$

Parameter β controls the delay/packet loss ratio while parameter α controls the ability of the algorithm to follow the changes in the delay. By experimenting with different values of α , β , and *playout_offset* in a real wireless environment we were able to chose the values (i.e. $\alpha = 0.998002$, $\beta = 2$, *playout_offset* = 40ms) that maximized rating factor R for all possible $AIFSN$ and CW_{min} settings.

3. EXPERIMENTAL RESULTS

Experiments covered 3 background traffic loads (1, 2, 3Mbps) 4 packetization schemes for background (256Bytes, 512Bytes, 1024Bytes and 1500Bytes packets)

Figure 2. Quality of voice transmission and effective throughput of 1Mbps background traffic vs $AIFSN_{[AC_BK]}$

Figure 3. Quality of voice transmission and effective throughput of 2Mbps background traffic vs $AIFSN_{[AC_BK]}$

Figure 4. Quality of voice transmission and effective throughput of 4Mbps background traffic vs $AIFSN_{[AC_BK]}$

and 14 settings of the $AIFSN_{[AC_BK]}$ parameter: 2, 3 ...14, and 15 time slots. Figures 2, 3 and 4 shows the average voice transmission quality (at wireless and wired interface) calculated for all 15 VoIP terminals and effective throughput (goodput) as a function of $AIFSN_{[AC_BK]}$ for three background traffic loads (1Mbps, 2Mbps, and 4 Mbps respectively).

It can be seen that voice transmission at the wireless network can be effectively prioritized over data by tuning the $AIFSN_{[AC_BK]}$. Increasing $AIFSN_{[AC_BK]}$ essentially promotes the AC_VO queue at the expense of the AC_BK queue in terms of probability access.

The bigger the difference in $AIFSN$ values, the easier it is for the AC_VO queue to win transmission opportunities from the AC_BK. As a result, transmission impairments (delay, jitter and packet loss) are reduced and the overall transmission quality is improved. For example, when the $AIFSN$ difference between AC_VO and AC_BK was 6 ($AIFSN_{[AC_BK]}=8$ and $AIFSN_{[AC_VO]}=2$), all VoIP stations could experience at least "tool" voice transmission quality (indicated by $R \geq 70$) for all examined background traffic loads and packetization schemes. Conversely a substantial reduction in the background traffic goodput was observed. In some cases (i.e. the 256 Bytes background packets load) the goodput of the background traffic was almost halved. Increasing the $AIFSN$ difference between AC_BK and AC_VO further penalizes background traffic by making it more difficult to win transmission opportunities.

4. CONCLUSIONS

In this paper we have experimentally evaluated the capability of the new 802.11e MAC protocol to support voice calls in a mixed voice/data transmission over WLANs. In our experiments we have focused on the contention-based mode of MAC operation called Enhanced Distributed Channel Access (EDCA) and more specifically on one quality enhancement parameter that controls the arbitration interframe space (AIFS), i.e. $AIFSN$ parameter.

Our results show that the tuning of the $AIFSN$ parameter can improve the quality of voice transmission at the wireless network while reducing the goodput of the background data traffic. For example, when the $AIFSN$ difference between AC_VO and AC_VO was 6 ($AIFSN_{[AC_BK]}=8$ slots and $AIFSN_{[AC_VO]}=2$), all fifteen VoIP terminals could experience at least "toll" voice transmission quality (indicated by $R \geq 70$) in the presence of the heavy background traffic injected to the network.

The $AIFSN$ differentiation is an effective mechanism for voice prioritization over data because of the very existence of discrete instants of times (protected slots represented by the $AIFSN$ difference) where a lower number of stations may compete and access the channel. This increases the effectiveness of the overall random access mechanism for the high-priority stations [15].

To our knowledge, this is the first experimental demonstration of voice prioritization in the real 802.11e WLAN network from the perspective of end-to-end speech transmission quality and end user satisfaction.
