Dear Author

The following queries have arisen during the editing of your manuscript and are identified on the proofs. Unless advised otherwise, please submit all corrections using the CATS online correction form.

AQ1. Please fill in correct page number.
AQ2. Please provide the manufacturers and their locations for SPSS version 17 and SigmaPlot version 8.0 software.
AQ3. Please provide a declaration of interest statement. All articles in Informa Healthcare journals should acknowledge any support/funding received by the authors to carry out the study, or any other commercial relationships relevant to the article’s subject matter. If no funding has been received, a statement explicitly declaring no conflict of interest is required.
AQ4. Please provide the volume number and page range for this work.
AQ5. Please provide the volume number and page range for this work.
AQ6. Please verify that HF{ is correct as shown.
AQ7. Currently your figures will appear in black and white for the print edition. If you would like to pay for figures 1A, 1B, and 2 to print in color, please indicate so that we may request a cost estimate.
Augmentation of Macular Pigment Following Supplementation with All Three Macular Carotenoids: An Exploratory Study

ABSTRACT

Purpose: At the macula, the carotenoids meso-zeaxanthin (MZ), lutein (L), and zeaxanthin (Z) are collectively referred to as macular pigment (MP). This study was designed to measure serum and macular responses to a macular carotenoid formulation.

Materials and Methods: Ten subjects were recruited into this study (five normal and five with early age-related macular degeneration [AMD]). Subjects were instructed to consume a formulation containing 7.3 mg of MZ, 3.7 mg of L, and 0.8 mg of Z everyday over an eight-week period. The spatial profile of MP optical density (i.e., MPOD at 0.25°, 0.5°, 1°, and 1.75°) was measured using customized heterochromatic flicker photometry, and a blood sample was collected at each study visit in order to analyze serum concentrations of MZ, L, and Z.

Results: There was a significant increase in serum concentrations of MZ and L after two weeks of supplementation (p < 0.05). Baseline serum carotenoid analysis detected a small peak eluting at the same time as MZ in all subjects, with a mean ± SD of 0.02 ± 0.01 μmol/L. We report significant increases in MPOD at 0.25°, 0.5°, 1°, and average MPOD across the spatial profile after just two weeks of supplementation (p < 0.05, for all). Four subjects (one normal and three AMD) who had an atypical MPOD spatial profile at baseline had the more typical MPOD spatial profile (i.e., highest MPOD at the center) after eight weeks of supplementation.

Conclusion: We report significant increases in serum concentrations of MZ and L following supplementation with MZ, L, and Z and a significant increase in MPOD, including its spatial profile, after two weeks of supplementation. Also, this study has detected the possible presence of MZ in human serum pre-supplementation and the ability of the study carotenoid formulation to rebuild central MPOD in subjects who have atypical profiles at baseline.

INTRODUCTION

Age-related macular degeneration (AMD) is an eye disease that affects the central part of the retina called the macula and in its late form, results in loss of central vision. Late AMD is the most common cause of
blindness in developed countries.\textsuperscript{1,2} It is estimated that
the number of people suffering from AMD will continue
to increase, primarily due to increasing longevity.\textsuperscript{3,4} It is
now believed that both oxidative stress and cumulative
exposure to short-wavelength (blue) light are involved in
the aetiology of AMD.\textsuperscript{5–7}

The center of the retina has a distinct yellow color
attributable to the presence of a pigment known as
macular pigment (MP), and this coloration contrib-
uted to the original eponymous description of this
retinal region as the \textit{macula lutea} (or yellow spot).\textsuperscript{8,9} MP
comprises three dietary carotenoids \textit{meso}-zeaxanthin
(MZ), lutein (L), and zeaxanthin (Z).\textsuperscript{8–10} There is now
a biologically plausible rationale, supported by a
growing body of evidence, in support of the view
that MP protects against AMD.\textsuperscript{7} For example, MP
has been shown to significantly reduce the amount
of blue light incident on the macula.\textsuperscript{11–14} Furthermore,
the antioxidant properties of MP's constituent caro-
tenoids within the retina and elsewhere have been
demonstrated \textit{in vitro}.\textsuperscript{15,16}

L and Z are found in a typical western diet, in fruit
and vegetables (e.g., spinach, corn, orange peppers, red
grapes);\textsuperscript{17} whereas, MZ is believed to be generated
at the macula following a biochemical transformation
of L.\textsuperscript{18,19} MZ has also been identified in some less
commonly consumed foods including fish (e.g.,
salmon and trout), shrimp, and turtle fat\textsuperscript{20}; however,
to date and in the absence of supplementation with this
carotenoid, MZ has not been detected or reported in
human serum. From a scientific perspective, we were
interested to investigate how individuals respond to
an MZ-based supplement (even in combination with
the other macular carotenoids) as it has been reported
that there is an association between AMD and MP
profile\textsuperscript{21} and given that research has shown that MZ
is generated in the retina following L conversion. It
is possible that individuals lacking centrally located
MP require MZ to be provided in supplement form,
as such individuals could (perhaps) lack the capacity
to convert L to MZ within the retina.

There are several published studies reporting on
supplemental L and/or Z, and the impact of such
supplementation on MP levels and/or serum con-
centrations of these carotenoids (Table 1). In 1997,
Hammond et al. showed that a diet modified to
result in increased consumption of L and Z, for as
little as four weeks, could augment MP, with this
effect being maintained for several months follow-
ing resumption of a normal, unmodified diet.\textsuperscript{22} Of
note, two of the 11 subjects involved in that study
did not show a significant rise in MP optical density
(MPOD), despite a significant increase in serum L
concentrations. These subjects were termed "retinal
non-responders"\textsuperscript{7}, and it has been hypothesized that

this phenomenon may be due to a compromised
ability to capture and/or stabilize the macular
carotenoids in these individuals.\textsuperscript{7} Landrum et al.
investigated the effect of L supplementation (30 mg
per day) in two individuals over a 140-day period.\textsuperscript{23}
They found an increase in serum L concentrations
in both individuals, coupled with a parallel increase
in MPOD. A more recent investigation reporting on
a commercially available L-based supplement with
respect to macular and serum response in patients
who displayed features of AMD was performed by
Trieschmann et al. in 2007.\textsuperscript{24} In that study, the authors
concluded that supplementation with 12 mg of L and
1 mg of Z, combined with co-antioxidants, resulted
in a significant increase in MPOD at 0.5° eccentricity
and in the majority of subjects (average increase \textasciitilde 0.1
optical density units [ODU]).

Of note, there has only been one study to date
which investigated the effects of supplemental MZ on
MPOD levels in human subjects.\textsuperscript{25} That study, which
included 10 subjects, showed that a soya bean oil-
based supplement containing 14.9 mg of MZ, 5.5 mg
of L, and 1.4 mg of Z resulted in an average increase
of \textasciitilde 0.07 MPOD at 0.75° of eccentricity over a 120
day period.\textsuperscript{26} However, limitations of the study per-
formed by Bone et al. include: MPOD was measured
at only one point of retinal eccentricity (\textasciitilde 0.75°) and
would therefore not have been able to detect changes
in MPOD, if any, occurring at other retinal eccentrici-
ties (e.g., 0.25°, 0.5°, 1°, 1.75°), including the more
central eccentricities of 0.25° and 0.5°; no controls
were included in the study; small sample size (\textasciitilde n=10);
and serum concentrations of MZ was only measured
for two subjects.

Our study, the \textit{Meso}-zeaxanthin Ocular Supplemen-
tation Trial (MOST), was designed to evaluate MPOD
response, including its spatial profile (i.e., 0.25°, 0.5°,
1°, and 1.75°), and serum carotenoid response, in 10
subjects (five normal and five AMD), following con-
sumption of a dietary food supplement containing
all three macular carotenoids: MZ, L, and Z, in which
MZ was the predominant carotenoid. The limitations
of this pilot investigation are as follows: no controls
were included into the study; small sample size (\textasciitilde n=10); however, the entire spatial profile of MPOD
was assessed (see above) and serum concentrations of
MZ were analyzed for all 10 subjects.

\section*{METHODS}

\subsection*{Subjects}

This was a non-randomized and open labeled study.
All subjects signed an informed consent document.

and the experimental measures conformed to the Declaration of Helsinki. The study was reviewed and approved by the Research Ethics Committee, South East Region, Waterford Regional Hospital, Waterford, Ireland.

This study consisted of two groups; Group 1 (n = 5), inclusion criteria: male or female between the age of 18 and 60 years; no presence of ocular pathology; visual acuity of at least 6/18 in the study eye. Exclusion criteria: individuals outside age range 18–60 years; pregnancy; presence of ocular pathology; currently taking supplements containing MZ, L, or Z. Group 2 (n = 5), inclusion criteria: male or female; early AMD (defined using the International Classification and Grading System for Age-Related Maculopathy and Age-Related Macular Degeneration)\(^\text{26}\) in at least one eye with best corrected visual acuity of at least 6/18 in that eye, hereafter known as the study eye for this group. Exclusion criteria: currently taking supplements containing MZ, L, or Z; presence of ocular pathology other than AMD.

The mixture of carotenoids was manufactured by Industrial Organica SA, Monterrey, Mexico by isomerizing L obtained from marigold extracts. A proportion of the L was converted into MZ, and the small quantity of Z in the extract remained unchanged. The resulting composition was microencapsulated after diluting with rice starch. Each capsule contained 7.3 mg MZ, 3.7 mg L, and 0.8 mg Z. We used a carotenoid formulation containing high amounts of MZ, as this carotenoid is now commercially available and reports on its response in human subjects, to date, are limited. In addition, we now present a scientific rationale for supplementation with this carotenoid in our Introduction (see page 000, paragraph 1).

All subjects (in both groups) were instructed to take one capsule per day with a meal for 60 days. MPOD, including its spatial profile (i.e., 0.25°, 0.5°, 1°, 1.75°), was measured at baseline and at two week intervals (V1: Baseline; V2: 2 weeks; V3: 4 weeks; V4: 6 weeks; V5: 8 weeks) over the 60 days (see Method below). In Group 1, the eye with better visual acuity was chosen as the study eye; however, where both eyes had the same corrected acuity, the right eye was chosen as the study eye.

A blood sample was collected at each study visit for serum carotenoid analysis of MZ, L, and Z (see Methods below). Demographic, lifestyle, and vision information was also collected from each subject as follows: name, contact information, age, sex, BMI, smoking habits, lifestyle, medication, and vision history. Best corrected visual acuity (BCVA) was measured using logMAR.

### Serum Total L and Total Z analysis—Assay 1

Blood samples (6–8 mL) were collected from all patients on the same day as MPOD assessment. Serum was separated from blood by centrifugation (DESGA Starstedt–Gruppe, GC12) 2500 RPM for 10 min, and then aliquoted into two amber light-sensitive microcentrifuge tubes and stored at minus 70°C until time of analysis. A 400 μL aliquot of serum was pipetted into an amber light-sensitive microcentrifuge tube (1.5 mL total capacity). Ethanol (300 μL) containing 0.25 g/L butylated hydroxytoluene (BHT) and 200 μL internal standard (α-tocopherol acetate [0.25 g/L]) were added to each tube. Heptane (500 μL) was then added and samples were vortexed vigorously for 2 min followed by centrifugation at 2000 rpm for 5 min (MSC Micro Centaur, Davison & Hardy Ltd., Belfast, UK). The resulting heptane layer was retained and transferred to a second labeled amber light-sensitive microcentrifuge tube, and a second heptane extraction was performed. The combined heptane layers were immediately evaporated to dryness under nitrogen. These dried samples were reconstituted in 200 μL methanol (containing 0.25 g/L BHT), and 100 μL was injected for high-performance liquid chromatography (HPLC) analysis.

We used an Agilent 1200 series (Agilent Technologies Ltd., Dublin, Ireland) system with photodiode array detection at a wavelength of 450 nm. A 5 μL analytical/preparative 4.6 × 250 mm 201TP speciality reverse phase column (Vydac, Hesperia, California, USA) was used with an in-line guard column. The mobile phase consisted of 97% methanol and 3% tetrahydrofuran. The flow rate was 1 mL/min, and the total run time was 15 min.

DSM Nutritional Products (Basel, Switzerland) provided total L (TL) and total Z (TZ) standards to generate response factors that were used to calculate serum concentrations of TL and TZ. An internal standard, α-tocopherol acetate, made up in ethanol (0.25 mg/L) was used to correct for recovery of extractions for HPLC analysis and assist quantification. All chromatograms were integrated manually by drawing a baseline and dropping perpendicular lines to quantify the peaks of interest (Figure 1A). All carotenoid peaks were integrated and quantified using Agilent ChemStation software. Figure 1A shows a typical chromatogram generated from the above described assay.

### Serum MZ Analysis—Assay 2

Assay 1 outlined above resulted in separation of TL and TZ. The eluent that corresponded to the peak of
TZ from assay 1 was collected from the waste line (fraction 1) and evaporated to dryness under nitrogen. Fraction 1 also contained some TL, as TL and TZ eluted close together, which made it difficult to collect just TZ from the waste line. All dried down samples were then reconstituted in 50 μL of n-hexane-isopropanol (90:10) and 40 μL was injected onto the 10 μm Chiralpak™ AD column (250 × 4.6 mm; Chiral Technologies Europe, France) protected by a Chiralpak™ guard column and a 2 μm filter. In order to achieve separation of the Z isomers (Z and MZ), a flow rate of 0.8 mL/min with the following gradient elution: starting at 90% n-hexane and 10% isopropanol, and increasing to 95% n-hexane over 30 min was used. Integration was manually carried out on the resulting chromatogram from assay 2 by drawing a baseline between ~13 and ~30 min and then dropping a perpendicular line to quantify the proportions of Z and MZ from their peak areas. The proportions of the Z isomers were assumed to be the same as in the TZ fraction from the column of assay 1, which enabled calculation of the individual amounts of Z and MZ in the TZ fraction. A sample chromatogram showing the MZ and Z peaks is presented in Figure 1B.

**Macular Pigment Optical Density**

MPOD was measured using the Macular Metrics Den-sitometer™, developed by Professor B. R. Wooten of Brown University, Providence, Rhode Island, USA, using heterochromatic flicker photometry (HFP). The
device was modified from the one described originally. Two different techniques for measuring MPOD using this device were employed for normal subjects (Group 1—"method of adjustment") and AMD subjects (Group 2—"bracketing method"), and are described below. We used the bracketing procedure for the AMD subjects as we find this procedure more suitable for older subjects (see below). All subjects were trained how to perform the HFP task at their first study visit. MPOD data was not recorded until subjects demonstrated a high level of understanding of the task. Reliability and reproducibility of MPOD measurements obtained using the Macular Metrics Densitometer™ have previously been reported.

**Background Common to Both Techniques**

In order to measure MPOD, the subject views a stimulus that alternates between a wavelength band absorbed by MP and one that is not. The radiance of the wavelength band absorbed by MP is adjusted in order to minimize the subjects’ percept of flicker. The range of alternation rates where flicker is not perceived is called the null zone. Primarily because of inter-individual differences in temporal (e.g., flicker) sensitivity, it is optimal to customize the HFP task for each subject by selecting the alternation rate to achieve a null zone and a precise setting. This has been termed as customized HFP (cHFP).

The first methodological consideration when using cHFP is selecting the appropriate flicker rate. Selecting the best flicker rate for each subject enables one to accommodate the variation in flicker sensitivity due to factors such as age and disease. If differences among subjects in flicker sensitivity are not accounted for (i.e., a fixed flicker frequency is used), then a subject with low flicker sensitivity (i.e., low critical flicker fusion frequency—CFF) will most likely experience a large null flicker zone. Alternatively, a subject with a high CFF may not be able to eliminate flicker from the test target, which would make the task difficult to complete.

Predicted optimal HFP flicker frequencies were estimated in order to facilitate good subject performance and reduce measurement error. To achieve this, we used an age-guided algorithm to estimate optimal HFP flicker frequencies for all the measurements performed (i.e., the measurement locus at 0.25°, 0.5°, 1°, 1.75°, and reference locus at 7°). This algorithm was informed by many years’ experience with the Densitometer™ at several different laboratories (see Table 2).

The second methodological consideration involves a test stimulus configuration in which the radiances of the two alternating components are inverse-yoked. In other words, when the blue component is adjusted to be more intense, the luminance of the green component is commensurately decreased, and vice versa. This procedure keeps the brightness of the test stimulus relatively constant. This approach is regarded as an improvement because some subjects find changes in brightness distracting when they perform the task.

In this study we measured the spatial profile of MP at four different retinal eccentricities: 0.25°, 0.5°, 1°, and 1.75° with a reference point at 7°. The targets and fixation points used for each retinal eccentricity measured were as follows: the 0.25° and 0.5° eccentricities were measured using a 0.5° and 1° diameter disc with a 5 min black fixation point at the center; the 1° and 1.75° eccentricities were measured using a 20 min-wide annuli with mean radii corresponding to those eccentricities were used with a centrally fixated 5 min black fixation point. The 7° reference measurement was a 2° diameter disc located 7° nasally with reference to a 5 min red fixation point (Figure 2). For the purpose of this study, we assume that flicker perception is dominated by the edges of the disc-shaped stimuli used in each instrument, although other research has suggested that this may not be the case.

OFF = optimal flicker frequency; 0.25° = MPOD measured at 0.25° retinal eccentricity; 0.5° = MPOD measured at 0.5° retinal eccentricity; 1° = MPOD measured at 1° retinal eccentricity; 1.75° = MPOD measured at 1.75° retinal eccentricity; 7° = MPOD measured at 7° retinal eccentricity. This algorithm developed by Nolan and Stringham was used to estimate optimal HFP flicker frequencies for each retinal locus, including the reference locus.
Macular Pigment Augmentation with Meso-Zeaxanthin

The subject repeated the test as above. This procedure was repeated on four more occasions and the radiance values were recorded in the MPOD log form. The same procedure was repeated for measurements (see above) at the following retinal eccentricities 0.25°, 1°, 1.75°, 7° (Figure 2). MPOD was then calculated using the log ratio of the measurement radiance values with respect to the reference radiance values obtained for each subject at 7°, using a method of adjustment MPOD calculator provided by Macular Metrics (Providence, Rhode Island, USA).

Of note, if the subject reported that there was no null flicker zone, the examiner increased the flicker frequency by two Hz. If the subject reported a very wide null zone then the flicker frequency was reduced by two Hz. These steps were repeated if necessary.

**Bracketing Method—Group 2**

The “bracketing method” developed by members of the Macular Pigment Research Group, Waterford, Ireland (Dr. John M. Nolan, Dr. Edward Loane) and Professor B.R. Wooten of Brown University, US (Densitytometer™ inventor), allowed us to obtain quick, but accurate and customized, MPOD values for Group 2 and is described below.

A diagrammatic representation of the initial test stimulus was used to familiarize the subject with the nature of the task (Figure 2). The examiner selected the target required to measure MPOD at 0.5° retinal eccentricity (1° stimulus (Figure 2)). The subject was instructed to place his/her study eye at the viewing eyepiece and the examiner ensured that the tilt of the main unit allowed comfortable viewing for the subject. The appropriate flicker frequency was set for the subject’s age. The examiner set the radiance button all the way to the left (i.e., lowest blue light intensity). The examiner then pushed a button that electronically, smoothly and continuously altered the blue/green ratio until the subject reported that there was no flicker. The radiance value obtained was recorded and this same procedure was repeated on four more occasions and recorded in the MPOD log form. The examiner set the radiance button all the way to the right (i.e., highest blue light intensity) and repeated the test all the way to the right (i.e., highest blue light intensity) and repeated the test four times as above. This completed the first part of the measurement (ten radiance values obtained in total, five approaching from the lowest blue light intensity and five approaching from highest blue light intensity). The same procedure was repeated for measurements (see above) at the following retinal eccentricities 0.25°, 1°, 1.75°, 7°, and MPOD was calculated using the log ratio of the measurement radiance values with respect to the reference radiance values obtained for each subject at 7°, using a bracketing procedure MPOD calculator provided by Macular Metrics (Providence, Rhode Island, USA).
RESULTS

The demographic, lifestyle, baseline macular serum carotenoid concentrations, and baseline MPOD data for the entire study group, Normal subjects (Group 1) and AMD subjects (Group 2) are presented in Table 3. As seen from this table, age was the only variable for which a statistically significant between group difference was observed ($p=0.001$).

Alterations in Serum Macular Carotenoid Concentrations Following Supplementation

We conducted a repeated measures analysis of variance for serum concentrations of MZ, TL, TZ, and Z quantified at each of the five study visits using a general linear model approach. The results are summarized in Table 4; the $p$ values displayed in the final column of this table were obtained using the Huynh-Feldt correction for sphericity. Use of the more conservative Greenhouse-Gesser correction would have led, in all cases, to the same conclusions regarding statistical significance. It is clear from Table 4 and the mean plots of Figures 3, 4, and 5 that the serum concentrations of MZ, TL, and TZ increase significantly with time; whereas, there was no significant time effect for serum concentrations of Z ($p=0.909$) (Table 4, Figure 6). Post hoc analysis (paired samples $t$-tests) revealed that the significant increase from baseline was present after two weeks of supplementation (paired samples $t$-tests) revealed that the significant increase from baseline was present after two weeks of supplementation (TL: $p<0.05$; TZ: $p<0.05$, and Z: $p=0.01$). The data for each individual subject are presented in Table 5.

Alterations in the Spatial Profile of MPOD Following Macular Carotenoid Supplementation

We conducted a repeated measures analysis of variance for MPOD (at 0.25°, 0.5°, 1°, 1.75°, and average MPOD for all these eccentricities) measured at each of the five study visits using a general linear model approach. The results are summarized in Table 6; the $p$ values displayed in the final column of this table were obtained using the Huynh-Feldt correction for sphericity. Use of the more conservative Greenhouse-Gesser correction would have led, in all cases, to the same conclusions regarding statistical significance. It is clear from Table 7 and the mean plots of Figures 7 that MPOD at 0.25°, 1° and average MPOD across the retina all increase significantly with time; whereas, there was no significant time effect for MPOD at 0.5° and 1.75° throughout the study period ($p=0.101$ and $p=0.61$). Of note, the biggest increase seen in MPOD...

Values represent mean ± SD; N = 9 (as one subject, 10, was unable to use the Densitometer and was, therefore, unable to have her MPOD measured); MPD = macular pigment optical density; V1 = visit 1, V2 = visit 2, V3 = visit 3, V4 = visit 4, V5 = visit 5; 0.25 = 0.25° retinal eccentricity; 0.5 = 0.5° retinal eccentricity; 1.0 = 1° retinal eccentricity; 1.75 = 1.75° retinal eccentricity; Total average = average MPOD for all eccentricities. The p-values represent repeated measures ANOVA for the 5 study visits, with Huynh-Feldt corrections for lack of sphericity.

The Relationship between Alterations in MPD Spatial Profile and Alterations in Serum Carotenoid Concentrations

In this study, the following all showed significant increases with time: serum MZ, serum TL, and serum TZ, MPOD at eccentricities at 0.25°, 1°, and also average MPOD across the retina (i.e., 0.25°, 0.5°, 1°, 1.75°) (see repeated measures results above, Figures 3, 4, 5, and Tables 4 and 6, respectively). However, investigating change in serum concentrations (for V2-V1) in each of MZ, TL, and TZ with respect to change in MPOD at 0.25°, 1°, and average MPOD, we found that, in every case, there is an inverse correlation between these variables (r = -0.538 to -0.805, e.g., V2-V1 serum concentrations of MZ vs. V2-V1 MPOD at 0.25°; r = -0.538, p = 0.135, Figure 8A). The fact that some of these correlations were not statistically significant can be ascribed to the small sample size of the current study. Of note, the strongest inverse

Values represent mean; N = 9 (as one subject, 10, was unable to use the Densitometer and was, therefore, unable to have her MPOD measured); S = Subject; V1 = visit 1, V2 = visit 2, V3 = visit 3, V4 = visit 4, V5 = visit 5; 0.25 = 0.25° retinal eccentricity; 0.5 = 0.5° retinal eccentricity; 1 = 1° retinal eccentricity; 1.75 = 1.75° retinal eccentricity; Av = average MPOD across entire spatial profile (0.25°, 0.5°, 1°, 1.75°); MPOD measured in optical density units.
correlation was seen for TZ (MZ + Z combined), which was statistically significant ($r = -0.805$, $p = 0.009$).

Interestingly, however, and for MZ only, the correlation is much closer to zero when we compare V5-V1 change rather than V2-V1 change (i.e., V5-V1 serum concentrations of MZ vs V5-V1 MPOD at 0.25°: $r = -0.028$, $p = 0.943$, Figure 8B); whereas, for TL and TZ the change in serum concentrations of these carotenoids versus the change in MPOD at 0.25° remained inverse at visit 5 ($r = -0.434$ and -0.671, respectively).

Typical versus Atypical MPOD Spatial Profile

Recent studies have been concerned with the spatial profile and distribution of MPOD. Of note, in the present study, four subjects (one Normal subject [Group 1]—Subject 5; and three AMD subjects [Group 2]—Subjects 6, 7, and 9) who displayed an atypical MPOD spatial profile at baseline (i.e., pre-supplementation), had the more typical MPOD spatial profile (i.e., highest MPOD at the center) after eight weeks of supplementation with MZ, L, and Z (i.e., the formulation used in this study). The MPOD spatial profile, averaged for the above four subjects, at pre(baseline) and post-supplementation (after 8 weeks) is presented in Figure 9 and their individual spatial profiles, at these two time points, are presented in Figure 10.

DISCUSSION

The MOST study was designed to investigate macular and serum responses to supplementation with the three macular carotenoids (in which MZ predominates: 7.3 mg of MZ, 3.7 mg of L, and 0.8 mg of Z), in normal healthy subjects and patients with early AMD. MPOD was measured using cHFP at 0.25°, 0.5°, 1°, and 1.75° retinal eccentricity with a reference point at 7°, every two weeks over a 60 day (two months) study period. A blood sample was also collected at each study visit in order to analyze serum concentrations of MZ, TL, TZ, and Z.
Supplementation studies to date have previously reported on serum response to supplementation with the macular carotenoids, with the majority of these studies reporting significant increases in serum concentrations of L and/or Z following supplementation with these carotenoids.\textsuperscript{22,23,25,27,39-52} Consistent with these previous studies, we report statistically significant increases in MZ and TL, after just two weeks of supplementation. Of note, average serum TL concentrations exhibited the highest average increase following supplementation with the study formulation, when compared to the other carotenoids (MZ and TZ). Our findings of a 1.3-fold increase in serum concentrations of L are consistent with previous studies, as our study formulation contained only 3.7 mg. For example, Bone et al. supplemented two subjects with 5 mg of L per day for 120 days and reported a 3-fold increase in serum concentrations of this carotenoid.\textsuperscript{51} Similarly, Berendschot et al. supplemented 8 subjects with 10 mg of L per day for 12 weeks and reported a 5-fold increase in serum concentrations of this carotenoid.\textsuperscript{39}

In our study, serum concentrations of Z showed no significant increase over the study period, and this may be attributable to the low amount of Z in the formulation (only 0.8 mg per capsule). Previous studies have reported significant increases in serum concentrations of Z following supplementation, albeit with a higher concentration of this carotenoid (e.g., Schalch et al. (2007): 12.6 mg Z for 17 weeks showed an increase of -1.09 µmol/L; Bone et al. (2003): 30 mg of Z for one year showed an increase of 0.52 µmol/L) in the preparation.\textsuperscript{43,51}

We report a statistically significant increase in serum concentrations of MZ, with a 3-fold increase observed over the 8-week study period (i.e., mean MZ: V1 = 0.02 µmol/L; mean MZ V2 = 0.06 µmol/L). However, it is important to point out that while MZ demonstrated a 3-fold increase in serum (from its baseline value), that following supplementation, when absolute average MZ serum concentrations are compared with average absolute serum L concentrations, we see that there is significantly more circulating L than MZ in serum (mean ± SD: 0.36 ± 0.12 µmol/L versus 0.06 ± 0.03 for L and MZ, respectively). Also, when our concentration increase is compared to the studies carried out by Thurnham et al. and Bone et al., it can be seen that our serum MZ response was much lower when compared to these studies (i.e., mean ± SD serum MZ concentration µmol/L = 0.209 ± 0.128 and 0.094 ± 0.071, respectively. However, it should be noted that the supplement used in the study by Thurnham et al. was suspended in oil; whereas, our study used a micro-encapsulated form of the supplement suspended in starch, which may account for, at least in part, the low serum response reported here, given that oil has been shown to promote carotenoid absorption.\textsuperscript{53}

The investigation by Thurnham et al. (2008) reported an average increase of 0.209 ± 0.128 µmol/L in serum concentrations of MZ (following supplementation with 8 mg per day of this carotenoid over a 22-day study period).\textsuperscript{27} Similarly, the study by Bone et al. observed augmented average serum concentrations of MZ (0.094 ± 0.071 µmol/L) following supplementation with 14 mg per day of this carotenoid over a 120-day period.\textsuperscript{25}

The study, conducted by Thurnham et al. (2008), reported on the absorption of MZ following supplementation with this carotenoid. Also, they compared the plasma responses to supplementation with a formulation containing MZ (Lutein Plus\textsuperscript{®}) with formulations containing L and Z (but not MZ), and reported that the increases seen in plasma L and Z concentrations were similar for each formulation, suggesting that MZ has little effect on absorption of L and/or Z. However, although Thurnham et al. reported that MZ did not decrease the absorption of L and Z, it is important to note that the study formulation used in that study contained more L than MZ (8 mg MZ, 10.8 mg L and 1.2 mg Z); whereas, in our study, the formulation contained more MZ than L (i.e., 7.3 mg MZ, 3.8 mg L and 0.8 mg Z). Thus, it may not be possible to extrapolate directly the effects of MZ on the absorption of L and Z to our study without further work. Of note, the studies conducted by Thurnham et al. and Bone et al. are the only two studies to date that have investigated serum absorption.
carotenoid response following supplementation with a preparation containing MZ, making any discussion with respect to our finding difficult. Also, no study to date has investigated and/or reported on histology or retinal function in response to MZ supplementation.

To our knowledge, no study to date has reported the presence of MZ in human serum pre-supplementation with this carotenoid. This notion is unsurprising, given that MZ is not found in a typical western diet (with the exception of some unusual foods and shellfish). However, in this current study, we detected the possible presence of MZ, albeit in minute concentrations, in all 10 subjects (mean ± SD MZ in μmol/L: 0.023 ± 0.007).

The possibility that MZ was in serum at baseline is a novel and interesting finding and may be explained as follows: MZ may be present in carotenoid-containing foods but as chiral chromatography is needed to separate MZ from Z, MZ may not have been detected since it is rarely used. Alternatively, MZ may be generated in serum following L transformation. However, the paucity of studies investigating any aspect of MZ in the diet and/or serum renders any discussion with respect to our finding that MZ is present in the serum of unsupplemented subjects difficult, and further study is warranted to fully investigate this assumption.

This current study is the first investigation into the spatial profile of MPOD (i.e., at 0.25°, 0.5°, 1°, 1.75°) following supplementation with all three macular carotenoids (MZ, L, and Z), which enabled us to measure change, if any, at the above degrees of retinal eccentricity, including the more central locations where MZ is located. We report increases in MPOD at 0.25°, 0.5°, 1°, and average MPOD across the retina (i.e., average of 0.25°, 0.5°, 1°, and 1.75°) during the study period, which became significant after just two weeks of supplementation. The rapid increase seen in MPOD in the current study is a somewhat novel finding as, to our knowledge, previous studies have not measured and/or reported on MPOD after two weeks of supplementation. In other words, previous studies to date have only reported on change in MP...
levels, if any, after four weeks of supplementation and beyond.

Our findings are consistent with a study conducted by Hammond et al. (1997), who reported significant MPOD augmentation following dietary modification (i.e., corn 0.4 mg L and 0.3 mg Z and spinach 10.8 mg L and 0.3 mg Z) after just four weeks of dietary intervention.22 Our observation is also consistent with previous reports that have investigated MP response to macular carotenoid supplementation (Table 1). In contrast, however, we found no significant augmentation of MPOD at 1.75° eccentricity. Also, and of interest, we observed the greatest increase in MPOD at 0.25°, with a mean ± SD increase of 0.16 ± 0.05 ODU at this eccentricity. Of note, no study to date has measured MPOD at this eccentricity following supplementation with MZ, L, and Z, and, therefore, it is difficult to make direct comparisons with other reports. It is likely that the significant increase seen in central MPOD in this study may be due to either MZ and/or L, especially given that MZ and L demonstrated significant responses in serum concentrations; however, with respect to MZ, this novel finding is interesting given that MZ is the dominant carotenoid in the study formulation (i.e., 7.3 mg [62%]) and given that the ratio of MZ to L, and the ratio of MZ to Z, is greater at the center of the fovea. For example, in 1997, Bone et al. reported that the proportions of MZ:Z in the central 3 mm of the macula was 0.83 which decreased with increasing distance from the fovea.19 Also, it is important to note that although the mean concentration of MZ was only 0.06 μmol/L at visit 2, this represents ~160 × 10^3 ng of MZ per 5 liters of blood. This observation is important, given that the amount of MZ in human donor eyes has been reported as ~7.7 ng and also given that an active binding protein for Z and MZ have been identified in retinal tissue.33–35 There has only been one other study to date that has measured MPOD following daily supplementation with MZ. That study, recently performed by Bone et al., in 2007, included 10 normal subjects, who were supplemented with 14.9 mg of MZ, 5.5 mg of L, and 1.4 mg of Z, for 120 days. Bone and co-workers reported a significant increase in MPOD at 0.75° of retinal eccentricity (mean increase = 0.07 ODU at this eccentricity) over the study period; however, in their study, MP was measured at only one retinal location (0.75°).23

As mentioned above, previous studies reporting on MPOD response to supplemental L and Z have reported parallel increases between these variables. In 1997, Hammond et al. showed MPOD augmentation following dietary modification after four weeks. Interestingly, two of the 11 subjects in that study did not respond at the macula, despite a significant increase found in serum concentrations of L and Z. Hammond et al. referred to these subjects as “retinal non-responders.”22 Our findings are consistent with this, we found that one of the 10 subjects recruited (Subject 4) into our trial did not respond at the macula, despite significant increases found in serum concentrations of MZ and L. In fact, and of particular interest, this subject displayed one of the highest increases in serum macular carotenoid concentrations. Also, this subject displayed a “typical” MPOD spatial profile and had the highest MPOD level (of subjects in this study), at baseline (i.e., 0.72 ODU at 0.25° retinal eccentricity). It is possible that this subject’s macula was saturated with MP, thus precluding the possibility of MP augmentation in response to supplementation. However, a longer supplementation period and follow-up may have resulted in MPOD augmentation for this subject.

Unexpectedly, we report an inverse trend between rises in serum concentrations of MZ, TL, and TZ (V2-V1) and increases in MPOD at 0.25°, 0.5°, 1° eccentricity and in average MPOD across the retina (V2-V1). Interestingly, however, this trend disappeared when we investigated the relationship between change in MPD (at 0.25°) from V5 and V1 and change in serum MZ from V5 and V1, whereas, it remained inverse for the relationship between change in MPOD (at 0.25°) from V5 and V1 and change in serum TL and TZ from V5 and V1. This somewhat unexpected and apparently contradictory finding may simply be explained by the fact that circulating MZ was captured by tissues more rapidly in subjects with depleted levels of this carotenoid at the macula and/or other target tissues (e.g., fat cells). This hypothesis is supported by our finding that the observed inverse trend between change in MPOD and change in serum MZ did not persist beyond V3. The above findings must, however, be interpreted with appreciation of the small sample size of our study and further study into this relationship is merited.

Another interesting finding from our study was the observation that four subjects (one normal and three AMD) exhibited an atypical MPOD spatial profile at baseline (i.e., secondary peak). Interestingly, however, following supplementation with MZ, all subjects exhibited the more typical MPOD spatial profile (exponential like decline),7,12 after just eight weeks of supplementation. In other words, it is tempting to hypothesise that the subjects who displayed the atypical MPOD spatial profile at baseline were exhibiting a relative lack of MP centrally (and, therefore, MZ), perhaps due to an inability to convert L to MZ at this location, but were able to rebuid their central MP peak with a supplement containing MZ.

While our findings are interesting, it is important to note the limitations inherent in our study design, and these include: the sample size of this trial was small.
(n=10), it was a non-blind open-labeled study, and
the period of follow-up was only 8 weeks (60 days).
Currently we are awaiting the results of a double
blind, randomized, placebo controlled trial (MOST 2
[ISRCTN60816411]) investigating serum and macular
response, in a normal healthy population, to a supple-
ment containing the three macular carotenoids (10.6 mg
of MZ, 5.9 mg of L, and 1.2 mg of Z). Also, a second
pilot study, in AMD patients over a longer period of
time will compare a formulation of L and Z only, with
a formulation of all three macular carotenoids (MZ, L,
and Z), and a follow-up on double blind randomized
trial comparing these formulations is also envisaged.
This study will further enhance our understanding of
serum and macular response to supplements contain-
ing the macular carotenoids in both normal and AMD
subjects.

In conclusion, we report significant increases in
serum concentrations of the macular carotenoids
following supplementation with a formulation con-
taining 7.3 mg MZ, 3.7 mg L, and 0.8 mg Z and also
a significant increase in MPOD (and alteration of its
spatial profile). Also, this pilot study has identified
the presence of MZ in human serum pre-supplemen-
tation, and the ability of this carotenoid formulation to
rebuild central MPOD in subjects who display atypical
profiles at baseline.
