Sol–gel and TiO<sub>2</sub>

#### ABSTRACT

In order to study the visible light photocatalytic activity of nitrogen doped titanium dioxide, the interaction between nitrogen dopant sources and titania precursors during sol–gel synthesis is investigated. N–TiO<sub>2</sub> was synthesised using the sol–gel method using 1,3-diaminopropane as a nitrogen source. Samples were annealed several temperatures and the percentage of rutile present determined by X-ray diffraction to be 0% (500 °C), 46% (600 °C), and 94% (700 °C). The reducing amounts of anatase at higher temperatures are studied using FTIR, which suggests the absence of any polymeric chains formed by the chelating agents, which would normally extend anatase-to-rutile transformation temperatures. Differential scanning calorimetry shows that crystallisation occurs before 500 °C, providing the crystalline form determined by XRD at 500 °C. Increased temperature also resulted in diminished visible light absorption capability, with only the 500 °C sample showing significant absorption in the visible region. XPS studies revealed that nitrogen remained within the TiO<sub>2</sub> lattice at higher temperatures. Consequent with the reduced visible light absorption capacity, photocatalytic activity also reduced with increased annealing temperature. Degradation kinetics of methylene blue, irradiated with a 60 W house-bulb, resulted in first order degradation rates constants of  $0.40 \times 10^{-2}$ ,  $0.19 \times 10^{-2}$ , and  $0.22 \times 10^{-2} \text{ min}^{-1}$  for 500, 600, and 700 °C respectively. Degradation of Degussa P25 was minimal under the same conditions, and that of undoped TiO<sub>2</sub> was  $0.02 \times 10^{-2} \text{ min}^{-1}$ . Similarly, using 4-chlorophenol under solar irradiation conditions, the N-doped sample at 500 °C substantially out-performed the undoped sample. These results are discussed in the context of the effect of increasing temperature on the nature of the band gap.

#### 1. Introduction

Titanium dioxide (TiO<sub>2</sub>) has become one of the most researched semiconductor materials due to the great promise it has shown in the photocatalytic oxidation of organic minerals [1,2]. The TiO<sub>2</sub> photocatalytic process involves the formation of highly oxidising radical species through the creation of an electron (e<sup>-</sup>), hole (h<sup>+</sup>) pair upon absorption of a photon of light that exceeds the band gap energy (3.2 eV or  $h\nu < 390 \text{ nm}$ ). [3] The powerful oxidising potential of TiO<sub>2</sub> was first demonstrated in 1972 by Fujishima and Honda through the photocatalytic splitting of water in a photoelectrochemical cell [4]. Despite the great promise shown by titanium dioxide, there are some drawbacks. The primary issue facing researchers associated with semiconductor photocatalysis is the large band gap of TiO<sub>2</sub> (3.2 eV) [5], meaning that only ultra-violet light ( $h\nu < 390 \text{ nm}$ ) can initiate the photocatalytic process,

therefore limiting the practical use of TiO<sub>2</sub> to  $\leq 5\%$  of the solar energy that reaches the earth's surface [5]. In order to overcome this difficulty it is necessary for researchers to modify the semiconductor band gap, thus facilitating visible light absorption and allowing the photocatalytic reaction to become more efficient under solar light irradiation. Asahi et al. [6] successfully demonstrated visible light absorption of a TiO<sub>2</sub> semiconductor through nitrogen doping. They concluded that substitutional N doping causes band gap narrowing through N 2p orbitals mixing with O 2p orbitals [6]. However, further investigations into what causes visible light absorption of N–TiO<sub>2</sub> has subsequently been carried out by a number of researchers. Ihara et al. [7] suggested that oxygen vacancies cause visible light activity and that the addition of nitrogen merely stabilises these oxygen vacancies. Visible light absorption through the addition of oxygen vacancies was also reported by Martyanov et al. [2]. However there now appears to be some agreement regarding the fine electronic details of N doped visible light absorption as reported by Irie [8] and Nakamura [9]. It is now believed that oxygen lattice sites within the TiO<sub>2</sub> crystal are substituted by nitrogen atoms [10,11]. The presence of these additional nitrogen atoms

E-mail address: [Suresh.pillai@dit.ie](mailto:Suresh.pillai@dit.ie) (S.C. Pillai).

form an occupied midgap (N 2p) level above the TiO<sub>2</sub> (O 2p) valence band. The N 2p band therefore acts as a step between the valence and the conduction band of the semiconductor, facilitating excitation of electrons from the N 2p mid-gap band to the conduction band upon irradiation with visible light [8,9].

Titanium dioxide is made up of TiO<sub>6</sub> octahedra [12]. The arrangement of these octahedra gives rise to three different polymorphs of titanium dioxide; anatase, rutile and brookite. Rutile is the thermodynamically stable form [13], while anatase and brookite are both metastable. Anatase and rutile are the most widely investigated polymorphs, with anatase being reported as the most photocatalytically active of the three [3,14,15]. Typically, anatase transforms to rutile under heat treatment (600–700 °C) [16,17]. Parameters that affect the anatase-to-rutile transformation include; particle shape/size [18], source effects [19], atmosphere [20], reaction conditions [21] and purity [22]. Surface defect concentration [23] and grain boundary concentration [24] dominate the anatase-to-rutile phase transformation temperature. It has been previously shown by researchers that N-doping supports the formation of O vacancies [2,25]. The presence of oxygen vacancies also enhances the anatase-to-rutile transformation [26–28], by facilitating the atomic rearrangement required for anatase-to-rutile transformation to occur [26].

The current paper reports a novel sol–gel technique for the synthesis of N–TiO<sub>2</sub>. X-ray diffraction shows how the crystallisation behaviour of the materials is affected by the inclusion of a nitrogen source (1,3-diaminopropane) in the sol–gel reaction. Spectroscopic studies show chelation of 1,3-diaminopropane to the titanium alkoxide precursor resulting in the stabilisation of the titanium isopropoxide monomer and inhibiting the formation of polymeric metal oxide chains. Electronic spectra indicate insertion of nitrogen into the TiO<sub>2</sub> lattice, and XPS reveals the chemical state of the atomic species as well as providing information on the mode of insertion (interstitial or substitutional) of atomic nitrogen within the TiO<sub>2</sub> lattice. Photocatalytic studies under irradiation with a 60 W light bulb reveal that the N-doped TiO<sub>2</sub> powders calcined at 500 °C have greater photocatalytic activity compared to the undoped samples prepared under similar conditions.

## 2. Experimental

A 1:0.5, titanium:nitrogen precursor suspension was synthesised as follows. Titanium tetraisopropoxide (10 mL) was added to 1,3-diaminopropane (1.39 mL, DAP) under stirring resulting in the formation of a white liquid–gel substance. Water (59.4 mL) was added to the gel to give a white paste. The paste suspension was allowed to stir for two hours before the liquid was filtered off leaving a white powder, which was then dried in air at 100 °C for 24 h. The dried powder was ground into a fine, white powder with mortar and pestle before being calcined at temperatures ranging from 500 to 900 °C for two hours at a ramp rate of 5 °C/min. A control TiO<sub>2</sub> sample was synthesised without the addition of 1,3-diaminopropane. Titanium tetraisopropoxide (10 mL) was added to water (59.4 mL) under stirring and the resulting powder was filtered, dried and calcined in an identical manner to TiO<sub>2</sub> prepared using nitrogen source.

Methylene blue is an accepted model organic pollutant for photocatalytic degradation studies and is used as an industrial standard (Japanese standard, JIS R 1703-2:2007) as such it was used to demonstrate the photocatalytic efficiency of the synthesised TiO<sub>2</sub> powders. Crystalline TiO<sub>2</sub> (60 mg) was added to methylene blue solution (50 mL, 1 × 10<sup>-5</sup> M) and stirred in the dark for 30 min to allow adsorption of the dye onto the photocatalyst before being placed under a 60 W light bulb and irradiated (radiation intensity is 1.2 W/m<sup>2</sup>) with continuous stirring. 5 mL aliquots were

Fig. 1. XRD of TiO<sub>2</sub> control and N–TiO<sub>2</sub> calcined at 600 °C.

withdrawn at timed intervals and the visible absorption spectrum was measured using a PerkinElmer Lambda 900 UV–vis spectrometer.

A degradation test was also carried out under simulated solar irradiation conditions in a Q-sun solar chamber (average radiation intensity is 0.66 W/m<sup>2</sup>). TiO<sub>2</sub> and 4-chlorophenol solution were exposed to light in the Q-sun, with aliquots taken at timed intervals and analysed by UV–vis spectroscopy. Crystalline TiO<sub>2</sub> (25 mg) was added to 4-chlorophenol solution (50 mL, 10 mg/L) and stirred in the dark for 30 min to allow for absorption of the compound onto the photocatalyst. The solution containing the photocatalyst was then exposed to simulated solar irradiated with continuous stirring.

A Siemens D 500 X-ray diffractometer, with a diffraction angle range  $2\theta = 20\text{--}80^\circ$  using Cu K $\alpha$  radiation was used to collect XRD diffractograms. XPS analyses were performed on a Thermo VG Scientific (East Grinstead, UK) ESCALAB Mk II spectrometer.

Surface area and pore size measurements were carried out using a Micrometrics Gemini VI Surface Area and Pore Analyser. The samples were degassed at 300 °C for 2 h prior to measurements. Scanning electron microscope images were obtained using a Hitachi SU-70 FE-SEM.

A PerkinElmer Lambda 900 UV–vis absorption spectrophotometer was used to record absorption and diffuse reflectance spectra, samples were mixed in KBr (1:20 sample/KBr) and pressed into a tablet, a KBr tablet made under the same conditions was used as a reference. Infrared spectra were obtained using a PerkinElmer GX FTIR spectrometer and recorded as a KBr disc (1:10 sample/KBr). Approximately 5 mg of sample was placed into an aluminium sample pan for DSC using an empty aluminium pan as a reference. All DSC were recorded on a Shimadzu DSC-60 between 25 °C and 600 °C at a ramp rate of 5 °C/min.

## 3. Results

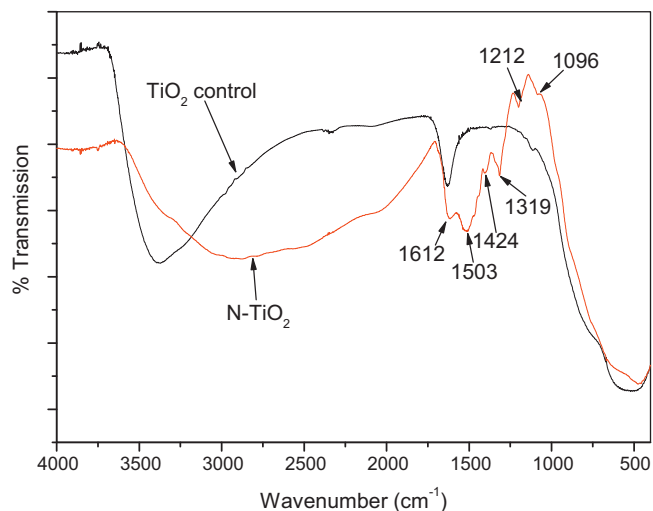

### 3.1. X-ray diffraction

The synthesised nitrogen doped and undoped titanium dioxide powders were calcined at temperatures 500–900 °C and the crystalline phases were determined using XRD (Fig. 1).

The XRD results show that at 500 °C, anatase is the only TiO<sub>2</sub> phase present for both samples. As the calcination temperature is increased to 600 °C rutile begins to form for N–TiO<sub>2</sub> but TiO<sub>2</sub> control is anatase only. At 700 °C, anatase and rutile are present for both

**Table 1**  
Phase composition of TiO<sub>2</sub> and N-TiO<sub>2</sub>.

Sample (Ti:N)	Calcination temp. (°C)	% Anatase	% Rutile
TiO <sub>2</sub> control	600	100	0
TiO <sub>2</sub> control	700	19	81
N-TiO <sub>2</sub> (1:0.5)	600	54	46
N-TiO <sub>2</sub> (1:0.5)	700	6	94

**Fig. 2.** Infrared spectrum of doped and undoped TiO<sub>2</sub> before calcination.

samples but there is a greater percentage (Table 1) transformation for TiO<sub>2</sub> control (0% to 81% rutile) compared to N-TiO<sub>2</sub> (46% to 94%) rutile. At 800 °C, complete phase transformation from anatase to the stable rutile has occurred for doped and undoped TiO<sub>2</sub>.

The inclusion of nitrogen increases the rutile percentage at 600 °C (46%) upon comparison with the control sample (0%). However, at 700 °C, TiO<sub>2</sub> control undergoes phase transformation to 81% rutile with N-TiO<sub>2</sub> retaining the anatase phase (6%). To determine the effect 1,3-diaminopropane on the crystallisation behaviour of the materials, spectroscopic investigation of the amorphous powders was carried out.

### 3.2. FTIR spectroscopy

To determine how 1,3-diaminopropane interacts with TTIP, infrared spectra of N-TiO<sub>2</sub> and TiO<sub>2</sub> control were recorded before the samples were calcined (Fig. 2) and the relative peaks were assigned (Table 2) [29–31].

Upon comparison of the spectral profile of TiO<sub>2</sub> control with N-TiO<sub>2</sub> an apparent difference is clear. The spectrum of N-TiO<sub>2</sub> gives several strong signals in the region 1000–1700 cm<sup>-1</sup> while for TiO<sub>2</sub> control a peak at 1631 cm<sup>-1</sup> representative of adsorbed H<sub>2</sub>O was the only peak in the same region. Both spectra show a broad peak from 400 to 1000 cm<sup>-1</sup> caused by a Ti–O stretch. X-ray crystallography has previously shown that both the nitrogen atoms from diaminopropane coordinate to metal centres to form a six membered ring [32–35]. The IR spectrum of N-TiO<sub>2</sub> shown in Fig. 2

**Table 2**  
Assigned frequencies for IR spectra of N-TiO<sub>2</sub> and TiO<sub>2</sub> control.

Observed frequency (cm <sup>-1</sup> )	Assignments
1612	NH <sub>2</sub> deformation
1503	NH <sub>2</sub> deformation
1424	CH <sub>2</sub> deformation
1319	CH <sub>2</sub> deformation
1212	CH <sub>2</sub> /NH <sub>2</sub> twist
1096	C–N stretch

**Fig. 3.** Infrared spectrum of N-doped TiO<sub>2</sub> calcined at 600 °C and 700 °C.

shows signals at 1612 and 1503 cm<sup>-1</sup> caused by NH<sub>2</sub> vibrations indicating that nitrogen is chelated to the titanium metal centre, increasing its coordination number to six and forming a chelated complex.

Modification of titanium alkoxides with chelating agents is known to promote thermally stable anatase phase at increased temperatures (>800 °C) [36,37]. However, the employment of chelating agents for the synthesis of stable anatase typically involves the formation of bridging structures that promote the formation of polymeric chains with extensive cross linking [38]. These chains remain stable throughout much of the condensation process, resulting in extended anatase-to-rutile transformation temperatures [39–41]. The opposite is occurring with the addition of diaminopropane and instead of the formation of a highly branched polymeric structure, monomeric titanium amine structures are formed that may interact with neighbouring titanium amines through hydrogen bonding. During the condensation process the monomeric structures with little or no cross-linking are structurally weak and will readily collapse under calcination to form rutile as was seen through XRD.

The infrared spectra of the calcined N-TiO<sub>2</sub> (Fig. 3) shows a peak located at 508 cm<sup>-1</sup>. The peak is at higher energy than would be expected for an undoped TiO<sub>2</sub> and have previously been assigned to the formation of O–Ti–N and N–Ti–N bond formation. [42] The infrared spectra of the N-TiO<sub>2</sub> calcined at 500 °C shows no peaks in this region, indicating that the Ti–N bond has not formed.

### 3.3. Differential scanning calorimetry

To examine the thermal events associated with the doped and undoped TiO<sub>2</sub> powders, differential scanning calorimetry (DSC) was carried out. A clear difference between TiO<sub>2</sub> control and N-TiO<sub>2</sub> was observed from the resulting DSC profile (Fig. 4).

An endothermic peak was observed at ~100 °C for both doped and undoped TiO<sub>2</sub>, which represents unbound water being removed from the TiO<sub>2</sub> surface [16]. However, for undoped TiO<sub>2</sub> the endothermic peak was of greater intensity indicating a greater capacity for the material to absorb water due to increased porosity. A minor exothermic peak at ~400 °C for TiO<sub>2</sub> control indicates crystallisation of amorphous TiO<sub>2</sub> to anatase. This was the only other thermal event of note observed for TiO<sub>2</sub> control. From XRD results, N-TiO<sub>2</sub> was found to be amorphous at 400 °C with anatase present at 500 °C. From DSC, a large endothermic peak beginning at ~400 °C for N-TiO<sub>2</sub> is indicative of the removal of 1,3-diaminopropane that was shown to be adsorbed through FTIR (Fig. 2). The removal of

Fig. 4. DSC of doped and undoped TiO<sub>2</sub>.

the amine leads into an exothermic peak below 500 °C representing the crystallisation of the material to anatase, which is in agreement with XRD results.

### 3.4. Diffuse reflectance

Upon visual inspection, N-TiO<sub>2</sub> calcined at 500 °C was seen to be capable of visible light absorption as seen by the pale yellow colour of the powder [25]. Light absorption characteristics of the powders were investigated using diffuse reflectance.

Diffuse reflectance spectra of the nitrogen doped TiO<sub>2</sub> powders calcined at 500 °C (Fig. 5) clearly show visible light absorption by the powders, indicating successful insertion of nitrogen into the TiO<sub>2</sub> lattice. Infrared and diffuse reflectance spectroscopic results indicate nitrogen titanium interactions both before and after calcination up to 500 °C. Powders calcined at temperatures  $\geq 600$  °C showed no visible light absorption, indicating band gap widening or ejection of nitrogen from the TiO<sub>2</sub> lattice. Nitrogen atoms can occupy either interstitial or substitutional sites within the TiO<sub>2</sub> lattice. Both types of nitrogen insertion are reported to give rise to localised states within the band gap of TiO<sub>2</sub> resulting in visible light absorption [25]. X-ray photoelectron spectroscopy (XPS) is commonly employed to determine the interactions between nitrogen and the TiO<sub>2</sub> lattice.

Fig. 5. Diffuse reflectance spectra of TiO<sub>2</sub> and N-TiO<sub>2</sub> calcined at 500 °C.

Fig. 6. N1s XPS spectra of (1:0.5) N-TiO<sub>2</sub> calcined at (a) 500 °C, (b) 600 °C.

### 3.5. X-ray photoelectron spectroscopy

The N1s spectra of N-TiO<sub>2</sub> calcined at temperatures 500 and 600 °C are shown in Fig. 6. X-ray photoelectron spectroscopy peak assignment for N-TiO<sub>2</sub> is still under some debate [25], but it is generally accepted that N1s peaks at 396–397 eV are representative of substitutional nitrogen [25,43] while peaks at binding energies  $>400$  eV are usually ascribed to NO (401 eV) or NO<sub>2</sub> (406 eV) indicating interstitial nitrogen [43]. The XPS spectra in Fig. 6, show peaks with binding energies of  $\sim 401$  eV which is higher than the typical N1s value but can be attributed to the binding of the 1s electron of N in the environment of O-Ti-N in lattice N-doped TiO<sub>2</sub>. The change in binding energy is due to the N substituting for oxygen in the O-Ti-O structure and the electron density around nitrogen becoming reduced compared to that of a TiN crystal, due to the presence of the oxygen atom [42]. This observation is consistent with literature on the oxidation of TiN surfaces [44].

Di Valentin et al. [25] employed density functional theory (DFT) to demonstrate interstitial nitrogen within anatase TiO<sub>2</sub>. Through DFT it was shown that there is no noticeable shift in the conduction or valence bands of the TiO<sub>2</sub>. With interstitial N, localised  $\pi$  character states are generated by the NO bond [25]. Two deep energy bonding states lie below the valence band and two antibonding N 2p states also lie above the valence band. It is the antibonding NO orbitals above the TiO<sub>2</sub> valence band that facilitate visible light absorption by acting as a stepping stone for excited electrons between conduction and valence bands (Fig. 7).

Fig. 7. Electronic structure for interstitial nitrogen doped TiO<sub>2</sub> [25].

**Table 3**  
Amount of nitrogen present in N-TiO<sub>2</sub> calcined at various temperatures (error ± 5%).

Ti:N precursor molar ratio	Calcination temperature (°C)	Nitrogen content (at%)
1:0.5	400	2.09
1:0.5	500	0.19
1:0.5	600	0.14
1:0.5	700	0.17
1:0.5	800	0.21

The atomic percentage of nitrogen in the N-TiO<sub>2</sub> samples calcined at increasing temperature is shown in Table 3. The results from Table 3 are in contrast with the observations made from diffuse reflectance spectra. XPS results reveal that the nitrogen content at calcination temperatures of ≥500 °C show no appreciable change, compared to the 600 °C. XPS does show a considerable drop in nitrogen content between 400 (2.09%) and 500 °C (0.19) which is in agreement with the removal of the adsorbed amine as shown through DSC.

The crystallisation behaviour of the TiO<sub>2</sub> was shown to be influenced by nitrogen as was the light absorption properties. N-TiO<sub>2</sub> is no longer capable of visible light absorption at calcination temperatures ≥600 °C. Disappearance of visible light absorption coincided with rutile formation. Through XPS it was shown that nitrogen

**Table 4**  
First order rate constants for methylene blue degradation with N-TiO<sub>2</sub>.

Sample	Ti:N molar ratio	Calcination temperature (°C)	Rate constant (min <sup>-1</sup> , ×10 <sup>-2</sup> )
N-TiO <sub>2</sub>	1:0.5	500	0.400
N-TiO <sub>2</sub>	1:0.5	600	0.190
N-TiO <sub>2</sub>	1:0.5	700	0.220
TiO <sub>2</sub> control	N/A	500	0.020
TiO <sub>2</sub> control	N/A	600	0.160
TiO <sub>2</sub> control	N/A	700	0.320
P25	N/A	N/A	0.005

is not ejected from the TiO<sub>2</sub> lattice at increased temperatures up to 800 °C. Diffuse reflectance results revealed a loss of visible light activity for the N-TiO<sub>2</sub> powders calcined at ≥600 °C which was believed to be caused by ejection of interstitial nitrogen at increased temperatures, however, XPS has shown that nitrogen remains within the lattice at all temperatures occupying interstitial sites [25,43]. X-ray diffraction results show the formation of rutile at temperatures ≥600 °C which leads to the conclusion that the formation of rutile is the reason for the blue shift in the absorption properties of the materials. Di Valentin et al. explain that a blue shift is observed with N-doped rutile because not only is the top of the TiO<sub>2</sub> valence band lowered (by 0.4 eV) but the inserted N 2p levels are also lower in energy than the valence band of pure rutile (0.05 eV) resulting in a band gap increase relative to pure rutile or anatase [25]. The increase in band gap energy observed between N-TiO<sub>2</sub> calcined at 500 °C compared with N-TiO<sub>2</sub> calcined at 600 °C agrees with the above theory and explains the occurrence of a blue shift upon rutile formation despite the presence of interstitial nitrogen.

The scanning electron microscope images show that the nitrogen doped titanium dioxide (Fig. 8(A)) has a porous structure in comparison to the undoped sample (Fig. 8(B)). The agglomerated particles are also found to be smaller than the undoped titania. The agglomerations of the N-TiO<sub>2</sub> are all less than 1 μm in size while the undoped samples have agglomerates over 2 μm in size. The surface area of the N-TiO<sub>2</sub> sample was found to be 20 m<sup>2</sup>/g, which is higher than the undoped sample of 2 m<sup>2</sup>/g. The smaller particle leads to a higher surface area which provides more sites for photocatalysis to take place. The N-doped material was found to have a pore size distribution of between 2 and 4 nm, resulting in the formation of a mesoporous material.

### 3.6. Photocatalytic activity

The photocatalytic performance of the synthesised powders under a household light source are shown in Table 4. As expected, the only sample that showed visible light absorbance (N-TiO<sub>2</sub>

Fig. 8. Scanning electron microscope image of (A) N-doped TiO<sub>2</sub> calcined at 500 °C and (B) undoped TiO<sub>2</sub> calcined at 500 °C.

**Fig. 9.** Degradation of 4-chlorophenol using N-TiO<sub>2</sub> calcined at 500 °C under irradiation from solar light in a Q-sun solar chamber.

calcined at 500 °C) was the best performing photocatalyst with a degradation reaction rate of  $0.4 \times 10^{-2} \text{ min}^{-1}$ . Nitrogen doped TiO<sub>2</sub> showed far greater photocatalytic activity under the 60 W light bulb when compared with the industrial standard, Degussa P25 which showed virtually zero degradation of methylene blue after 6 h of irradiation.

N-TiO<sub>2</sub> calcined at 700 °C shows slightly greater activity than N-TiO<sub>2</sub> calcined at 600 °C. Any photoactivity observed for N-TiO<sub>2</sub> calcined at 600 and 700 °C was attributed to the presence of the lower band gap energy rutile (3.0 eV or 400 nm).

For the degradation of 4-chlorophenol, a model organic pollutant, the N-doped titania sample calcined at 500 °C was again found to be the most efficient. Under irradiation in a solar chamber, complete degradation of the 4-chlorophenol was found to occur in 2 h. No degradation was observed for the control sample prepared under similar conditions. The samples prepared at higher temperatures did not show any photocatalytic activity, this is due to the formation of rutile at these higher temperatures, which is not photocatalytically active in the N-doped samples.

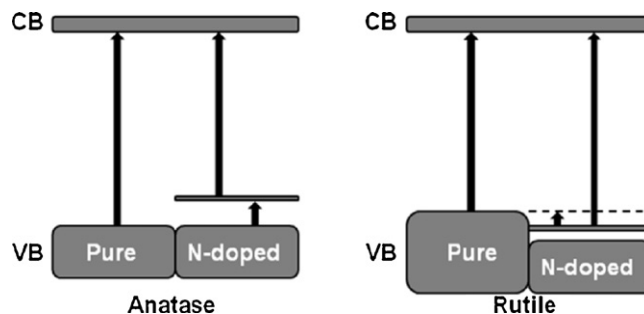

A degradation plot of 4-chlorophenol under irradiation from a solar chamber is shown in Fig. 9. The rate of degradation was found to obey first order kinetics and the rate constant was calculated from the first order plot. Lists of rate constants are shown for 4-chlorophenol degradation in Table 5.

#### 4. Discussion

FTIR results indicated the chelation of 1,3-diaminopropane to titanium tetraisopropoxide through nitrogen–titanium bonding and from XRD, DSC and XPS it could be seen that at calcination temperatures exceeding 400 °C, adsorbed 1,3-diaminopropane is removed and crystallisation occurs. Diffuse reflectance results demonstrated the ability of N-TiO<sub>2</sub> calcined at 500 °C to absorb visible light. However, N-TiO<sub>2</sub> samples calcined at temperatures in excess of 500 °C showed no evidence of visible light absorbance indicating band gap widening. Through XPS it was determined that

**Table 5**  
First order rate constants for 4-chlorophenol degradation with N-TiO under solar irradiation.

Sample	Ti:N molar ratio	Calcination temperature (°C)	Rate constant (min <sup>-1</sup> , ×10 <sup>-2</sup> )
N-TiO <sub>2</sub>	1:0.5	500	0.900
TiO <sub>2</sub> control	N/A	500	0.030

**Fig. 10.** Schematic electronic structure [23] for pure and N-doped anatase and rutile polymorphs of TiO<sub>2</sub>.

nitrogen remained within the TiO<sub>2</sub> lattice at temperatures >500 °C so it can therefore be postulated that the loss of visible light absorption is caused by band gap widening. A blue shift in the absorbance properties of N-TiO<sub>2</sub> samples calcined at  $\geq 600$  °C coincides with the formation of rutile as shown through XRD. For N-TiO<sub>2</sub>, rutile (46%) was formed after calcination at 600 °C. Although rutile possesses a smaller band gap than anatase, a blue shift is observed with rutile formation. This can be explained through the inclusion of nitrogen within rutile crystals. Di Valentin et al. [25] explain that a blue shift is observed with N-doped rutile because not only is the top of the TiO<sub>2</sub> valence band lowered (by 0.4 eV) but the inserted N 2p levels are also lower in energy than the valence band of pure rutile (0.05 eV) resulting in an overall blue shift in the optical absorption of N-doped rutile of  $\sim 0.1$  eV (Fig. 10).

Anatase-to-rutile transformation can be dominated by effects such as defect concentration [21]. Nitrogen defects within the TiO<sub>2</sub> lattice, may act as nucleation sites for the anatase-to-rutile transformation, facilitating the formation of rutile at low temperatures ( $\geq 600$  °C). Induced low temperature rutile formation in the presence of nitrogen is contradictory to previous reports by this group [41]. It has been previously observed that using urea as a nitrogen source alters the condensation pathway, extending the temperature at which rutile forms [42]. However, the current study shows that 1,3-diaminopropane stabilises titanium tetraisopropoxide as a monomer which will contribute to the low temperature formation of rutile. The increased surface area of the N-TiO<sub>2</sub> sample (20 m<sup>2</sup>/g) compared to the control sample (2 m<sup>2</sup>/g) also contributed to the higher visible light active properties of N-doped samples. From the FESEM studies it was further evident that the particles of the N-doped samples were less agglomerated compared to the control samples.

Table 1 highlights the anatase/rutile percentages of the control TiO<sub>2</sub> sample as well as the nitrogen doped sample. At 600 °C TiO<sub>2</sub> (control) is 100% anatase. However, N-TiO<sub>2</sub> calcined at the same temperature (600 °C) has begun to transform into rutile (46%). Crystallisation results show that inclusion of nitrogen within the lattice reduces the anatase-to-rutile transformation temperature, which is accredited to nitrogen within the lattice acting as nucleation sites for the anatase-to-rutile transformation [42]. Substitutional nitrogen doping was also previously reported to improve the visible light photocatalytic activities of nitrogen doped anatase-rutile heterojunctions. However, in the current case the pure N-doped anatase annealed at 500 °C showed a better performance compared to an anatase–rutile mixture [43]. Another influencing factor for early rutile formation with nitrogen doped TiO<sub>2</sub> is the increased formation of oxygen vacancies. Several researchers have demonstrated that nitrogen promotes the formation of oxygen vacancies within TiO<sub>2</sub> [2,7]. Oxygen vacancies have also been widely reported to lower the anatase-to-rutile transformation temperature. Space is created within the crystal lattice with the presence of oxygen vacancies allowing ionic rearrangement to occur with greater ease,

which is necessary for the structural changes that occur during the anatase-to-rutile transformation [14,24–26].

## 5. Conclusions

Titanium dioxide was successfully doped with nitrogen to create a visible light active photocatalyst. 1,3-diaminopropane was chosen as a nitrogen source and through infrared spectroscopy it was determined that diaminopropane chelates to titanium forming a six membered ring, the chelated titanium amine results in the formation of titanium isopropoxide monomeric units that readily form rutile at low temperatures as shown through XRD. XPS and DSC results showed that the material retains the adsorbed amine up to 400 °C but at increased temperatures (500 °C) the material crystallises to anatase TiO<sub>2</sub> with nitrogen inserted into the crystal lattice, present in interstitial sites as shown through XPS. Diffuse reflectance spectra of N-TiO<sub>2</sub> calcined at 500 °C indicated the presence of N 2p bands between the valence band and conduction band of TiO<sub>2</sub> allow for visible light absorption by the material. However, upon calcination at ≥600 °C, N-TiO<sub>2</sub> is no longer capable of visible light absorption, which coincides with the formation of rutile. This was attributed to a band gap extension in N doped rutile. The photocatalytic degradation of methylene blue and 4-chlorophenol was carried out under irradiation from a household light bulb (60 W) and using a Q-sun solar chamber respectively. The N-TiO<sub>2</sub> prepared at 500 °C showed the highest amount of activity, higher than that of a control TiO<sub>2</sub> sample and of Degussa P25 TiO<sub>2</sub>.

## Acknowledgements

The authors wish to thank Science Foundation Ireland (SFI grant number 10/US/I1822) for supporting this investigation under the US-Ireland R&D partnership programme, CREST and Focas for lab and office facilities and equipment. The authors would also like to thank Dr. John Colreavy for reviewing the paper and providing valuable comments and Michael Whelan for providing the scanning electron microscopy images. The authors would like to acknowledge Enterprise Ireland (CFD/06/IT/326 and ARE/2008/0005) and Environmental Protection Agency (EPA) Ireland for funding.
