HIGHLIGHTS

- PICO review identified 40 distinct private groundwater interventions.
- Just one identified intervention associated with microbial contamination of private groundwater.
- Mean behavioural and knowledge attainment across interventions was 53% and 48%, respectively.
- Interventions in economically developed regions exhibited higher behavioural outcomes.
- Practical interventions allied with both large- and local-scale awareness-raising campaigns represent an optimum approach.

ABSTRACT

Groundwater contamination constitutes a significant health risk for private well users residing in rural areas. As the responsibility to safeguard rural private domestic groundwater typically rests with non-expert homeowners, interventions promoting risk mitigation and awareness represent the most viable means of preventing supply contamination. However, no global review or pooled analyses of these interventions has been undertaken to date. The current study sought to identify and quantify the performance of private well interventions from 1990 to 2018 via a global systematised review and pooled analysis. The PICO (Population-Intervention-Comparison-Outcome) approach was employed for literature identification. Relevant studies were statistically analysed across two quantitative outcome (performance) types, namely knowledge and behaviour, controlling for intervention characteristics and country development status. Mean behavioural and knowledge attainment across interventions was 53% and 48%, respectively, with interventions in economically developed regions exhibiting higher behavioural outcomes (56% vs. 45%) than those in developing regions. Geographically, interventions were located in southern or south-east Asia (n = 23), North America (n = 15), Central America (n = 1) and Africa (n = 1), with none identified in Australia/Oceania, Europe, or South America. Behavioural outcomes were significantly associated with presence of educational/research coordinator (p = 0.023), with these interventions attaining higher levels of efficacy (+74%) than those implemented by other coordinator types. Findings indicate that instructor-

led, practical interventions allied with both large- and local-scale awareness-raising campaigns represent an optimum approach for future private well risk interventions. Subsequent adoption of such interventions may lead to increased levels of private well maintenance and provide a point of reference for myriad water and health communication contexts.

1. Introduction

Groundwater is the most extracted raw material on earth and represents the largest global reservoir of accessible freshwater for human consumption, currently serving an estimated 2.2 billion people (Gleeson et al., 2016; Murphy et al., 2017). With a significant portion of historical groundwater abstraction occurring in the last 50 years due to rising populations and dwindling surface water resources, established reserves have become overexploited (Gorelick & Zheng, 2015). As a result, groundwater quality has become severely compromised in many regions, with improved supply management now regarded as a key environmental health challenge for the 21st century (Gorelick & Zheng, 2015; Jakeman et al., 2016). Much of the recent research pertaining to global groundwater management has focused on predicting and modelling aquifer withdrawals and developing options for recovery and restoration (Niu et al., 2014). Of more immediate concern is the widespread susceptibility of potable sources to contamination posing human health risks, particularly in light of shifting land-use patterns and climate change (Green et al., 2011; O'Dwyer et al., 2016; Andrade et al. 2018).

Unprecedented rates of groundwater abstraction in areas characterised by high geochemical concentrations, expanding agro-industrial activities and climate change-induced changes in precipitation patterns have resulted in the wide proliferation of chemical and microbial contaminants in groundwater supplies (Schwarzenbach et al., 2010; Gorelick & Zheng, 2015). An increasing number of well users worldwide have consequently suffered severe health impacts due to chronic exposure to naturally occurring chemicals such as arsenic and nitrate and contraction of waterborne diseases (Jakeman et al., 2016). Global estimates suggest that over 150 million people currently ingest arsenic from groundwater drinking supplies exceeding permissible limits set by the WHO (Ravenscroft et al., 2009). Moreover, a recent global review of groundwater-related enteric disease outbreaks identified 649 events within the published literature during the period 1948–2015 and a steadily increasing incidence of groundwater-related acute gastrointestinal infections (AGI) (Murphy et al., 2017). Rural populations relying on private, unregulated wells are particularly susceptible to illness due to the wide range of proximate contaminant sources (e.g. domestic wastewater treatment systems (DWWTSs), agriculture) and geographical/infrastructural obstacles (e.g. isolation from major population centres and services) hindering “top-down” groundwater management and policy implementation (Pearson et al., 2011; Valle Junior et al., 2014). Accordingly, private groundwater interventions (i.e. initiatives to promote source safety and protection) are being increasingly implemented in rural areas to compensate for the widespread absence of regulatory tools (Morris et al., 2016).

While many groundwater management challenges are frequently associated with socioeconomically “developing” regions, concomitant concerns are also reported in the more affluent “developed” nations (Shankar et al., 2014; WHO/UNICEF, 2015). Additionally, some of the most prevalent groundwater contaminants (e.g. naturally occurring arsenic) encountered in developing countries (e.g. Bangladesh) also occur in high concentrations in developed countries (e.g. United States) (Shankar et al., 2014; Henry & Suk, 2018). Conversely, rural regions in developed countries are

associated with their own suite of potential hazards to private groundwater; for example, DWWTS-originated contamination stemming from rapid exurban housing development and emerging organic contaminants (EOCs), e.g. industrial compounds, and intensive agriculture (Lapworth et al., 2012). In order to effectively minimise groundwater contamination and consequent health impacts on a global scale, it is important to acknowledge both regional commonalities and variations.

Due to the absence of private groundwater regulation in many territories, the onus to protect private rural groundwater largely lies with non-expert owners and users. Interventions entailing public engagement (e.g. information campaigns, well testing services) to promote protective behaviours and risk awareness may therefore constitute the most feasible approach to ensuring improved rural groundwater quality – irrespective of region of implementation (Kreutzweiser et al., 2011; Mitchell et al., 2012). The necessity for these initiatives has been highlighted in several previous studies reporting pronounced shortcomings in risk awareness and protective actions, with many recommending renewed or novel outreach strategies (Charrois, 2010; Malecki et al., 2017). However, in spite of the growing acknowledgement that enhanced engagement with private well users is necessary, benchmarks for effective private groundwater interventions (leading to “bottom-up” mitigation) remain elusive and existing frameworks inadequate (Mitchell et al., 2012; Hynds et al., 2018). Quantification of current success rates and outcome predictors associated with rural groundwater interventions may represent a benchmark for future hydrogeological investigations and management strategies addressing the intersect between groundwater and end-users. While previous studies have identified contextual factors surrounding well user outreach (e.g. Morris et al., 2016), to date, no broad empiric analysis of rural groundwater interventions and associated behavioural and knowledge outcomes exists in the literature. The current study responds to this deficit via a global systematised review and pooled-analysis to establish the performance of private well user interventions designed to engender increased source protection and risk awareness.

2. Methods

A systematised scoping review protocol was adapted and developed from previous studies (Elamin et al., 2009; Hynds et al., 2014). The review protocol was accepted and registered on PROSPERO (Registration Number CRD42017078019), and comprised four distinct process steps, namely: *Literature Identification* (Section 2.1), *Study Selection* (Section 2.2), *Data Extraction* (Section 2.3) and *Pooled Analysis* (Section 2.4).

2.1. Literature identification

The first stage of an evidence-based review process comprises development of an answerable question to facilitate identification of relevant literature (Moher et al., 2009). The present review was guided by the following research question:

What interventions have been employed to improve awareness and protective behaviour(s) among rural private groundwater users and what levels of success have been achieved?

Due to the significant public health dimension of private groundwater interventions, the research question and literature identification process employed the PICO (Population, Intervention, Comparison, Outcomes) approach (Schardt et al., 2007; Higgins & Green, 2011). The PICO method and its application within the current study, including explicit search terms and associated PICO components, are presented in Figure 1 and Table 1. In light of the multidisciplinary and global span of the review and consequent requirement for wide journal coverage, potentially relevant literature was searched using the Google Scholar search engine. While the authors acknowledge the weaknesses of Google Scholar as a systematic search tool (e.g. limited search algorithms and filters), assuring a blanket aggregation of studies was considered optimal for maximum article retrieval and deemed to negate these limitations (Haddaway et al., 2015). Databases characterised by a comparatively specialised, restricted focus (e.g. Scopus, PubMed) were hence not consulted (Falagas et al., 2008). A review period of 29 years (1990–2018) was used to ensure comprehensive capture of temporally relevant data. Search combinations incorporated a minimum of four individual search terms (one per PICO component) (Table 1).

Explicit eligibility (inclusion/exclusion) criteria were used for article screening (Table 2). Only peer-reviewed academic journal articles written in English evaluating measurable interventions intended for private groundwater supply users during or after 1990 were considered. Grey literature (e.g. technical reports, working papers, conference papers/abstracts, etc.) was excluded to avoid publication bias, skewed intervention coverage, and/or inadequate study design. Investigations located in non-rural (i.e. urban or peri-urban) areas and/or failing to present demarcated quantitative data specific to private well users were not considered appropriate for inclusion. Likewise, interventions not specifically directed at private groundwater sources and/or users were excluded.

2.2. Study selection (screening)

The literature search (SM, CM) returned 15,946 potentially relevant studies, of which 4,080 were retained for screening based on eligibility (Table 2). The first stage of literature screening was based on an independent assessment of article titles and abstracts (Figure 2), with 279 abstracts deemed to fulfil inclusion criteria. “Legacy” searches were subsequently undertaken to ensure identification of studies undetected during electronic searches. Follow-

Table 1

Literature review search terms and correspondent PICO classification and description.

Primary Term	Term Description	Search Terms
Population	Rural private groundwater supply (borehole, spring or well) users	Borehole users; groundwater supply; private groundwater; private well owners; spring water; tube wells
Intervention	National and subnational outreach strategies targeting private well users (information campaigns, workshops etc.)	Education; engagement; information campaign; intervention; outreach; risk communication
Comparison	Differences between interventions in type, region, reach etc.	Contamination; inspection; registration; sampling; testing; treatment
Outcomes	Impact on well user behaviour and knowledge	Awareness; behaviour; knowledge; risk prevention; risk reduction

Table 2

Eligibility (inclusion/exclusion) criteria employed for literature screening.

	Inclusion criteria	Exclusion criteria
Literature	Peer-reviewed academic journal articles	Grey literature
Language	English	Non-English
Population	Private groundwater supply users residing in rural areas	Surface water and public groundwater users + households residing in urban or peri-urban areas
Evaluation	Quantitative investigations of interventions intended to promote groundwater supply user stewardship	Investigations with insufficient or non-quantitative data relating to intervention outcomes
Period	1990–present	Pre-1990 (intervention and article)

ing omission of grey literature (-90 studies) and addition of relevant journal article abstracts/titles from study reference lists (+81 studies), 270 articles remained for the second phase of literature screening (full article analysis).

Full articles were analysed using established eligibility criteria, with studies independently assessed by three authors (SM, CM, PH) and, where divergence arose, iteratively deliberated until consensus was reached. The final stage of screening was predicated on suitability of interventions and evaluations, resulting in the inclusion of 31 articles containing 40 distinct interventions.

Figure 1. The PICO approach as applied for literature identification and data extraction in the current study.

Figure 2. Schematic of study selection protocol.

2.3. Data extraction

Overall, 74 variables were extracted under nine primary categories (Appendix). Interventions were coded with respect to country development status following the emergence of a natural dichotomy between high and low/medium development nations. The separation was deemed to increase accessibility for prospective private groundwater intervention coordinators, as interventions in countries of contrasting socio-economic interest, notwithstanding potential similarities/transferability, are likely to

differ in orientation and effectiveness (Oxman et al., 2009; Waddington et al., 2012).

Intervention reach (i.e. geographic extent of influence) was categorised with reference to the WHO's ExpandNet Framework for intervention scaling and divided into three classifications: large (national/state/regional), medium (sub-regional/county) and small (community/local) (WHO, 2009). Intervention mechanisms (i.e. constituent activities of overarching interventions) were categorised based on public engagement typologies developed by Rowe & Frewer (2005), with two mechanism types (*electronic*

and print) based upon uni-directional information flow from intervention coordinator to audience (recipient population) and one mechanism type (*interpersonal*) based upon reciprocal (bi-directional) information flow. A fourth mechanism type (*convenience*) was designated for intervention activities entailing direct support (e.g. provision of contaminant treatment system) and/or practical action (e.g. well installation) on behalf of well users. Classification of intervention stakeholders, i.e. coordinators (bodies responsible for implementing interventions) broadly emulated the stakeholder classes set out by Bunn et al. (2002), as follows: *community body*, *educational/research body*, *government body*, *non-profit body* and *other body*. Extracted outcomes comprised measured behaviours and knowledge levels explicitly related to well safety, maintenance and health risks and were selected based on their assigned importance to intervention objectives by study authors. Where primary behavioural and knowledge outcomes were not specified, multiple measures were combined and averaged for each respective outcome type.

Dummy variables were developed for seven data categories; in instances where relevant information (e.g. regulatory status of private groundwater supplies in intervention area) was not provided in articles but available elsewhere, relevant sources (e.g. UNDP Human Development Index) were consulted (UNDP, 2016). For numerical (continuous) variables (e.g. intervention duration), intervals and units of measurement were discretised into appropriate ranges. Upon completion of data extraction and division of interventions by country development status, 69 variables were retained for coding and analyses, with five variables (hydrogeological setting, intervention cost, presence of disease/illness, number of wells, well depth) excluded due to incomplete records (available in <50% of studies).

2.4. Pooled Analysis

Data were numerically coded and imported to *IBM SPSS Statistics 26* (Armonk, NY: IBM Corp) for statistical analyses. Descriptive statistical functions (i.e. box and whisker plots displaying the median, interquartile ranges and present extreme/outlier values and stem-and-leaf plots) were employed to detect outliers across results per outcome type (behaviour and knowledge). Upon removal of outliers, outcomes were analysed for normality through visual inspection of Q-Q plots and the Shapiro-Wilk test. As overall outcomes followed a normal distribution, parametric statistical testing was employed.

The Pearson chi-square test of independence was used to test for associations between dichotomous (e.g. developed/developing) and nominal (e.g. intervention type) categorical variables. One-way analysis of variance (ANOVA) tests were used to explore relationships between intervention characteristics (categorical variables) and outcomes (continuous variables). One-way ANCOVAs examined adjusted associations (study design and country development status) between intervention characteristics and knowledge and behaviour outcomes. Study design denotes presence or absence of baseline data in intervention evaluations. The level of significance was set at $p < 0.05$ by convention.

3. Results

3.1. Intervention characteristics

The review process yielded 40 distinct interventions (Figure 2), of which 58% ($n = 23$) were undertaken in southern or south-eastern Asia, with remaining interventions from the United States (28%, $n = 11$), Canada (10%, $n = 4$), Guatemala (3%, $n = 1$) and Uganda (3%, $n = 1$) (Table 3). Notably, no interventions from Eur-

ope, South America or the Australian sub-continent were identified (Figure 3). Chemical and microbial contaminants were reported in 83% ($n = 33$) and 3% ($n = 1$) of interventions, respectively, with remaining studies failing to specify contaminant type. Drilled boreholes comprised the majority (80%, $n = 32$) of private groundwater supplies for which interventions were reported. Well depths and local/regional (hydro)geological information was reported for just 18% ($n = 7$) and 13% ($n = 5$) of interventions, respectively. Six interventions were undertaken in areas currently subject to private groundwater regulation (United States), including mandatory well water testing transactions (10%, $n = 4$) and well construction standards (5%, $n = 2$).

Seven intervention types (i.e. distinct outreach strategies) were identified, with information campaigns (65%, $n = 26$) and well testing services (65%, $n = 26$) the most frequently implemented (Table 4). With respect to intervention reach, interventions were most often oriented at the subregional/county (medium) scale (43%, $n = 17$). Of the four intervention mechanism types (i.e. channels of engagement), the most commonly employed was convenience (83%, $n = 33$), followed by interpersonal (60%, $n = 24$), print (45%, $n = 18$) and electronic (25%, $n = 10$). Interventions were incentivised in 85% ($n = 34$) of cases, with incentives ranging from practical (e.g. provision of water sample bottle) to financial (e.g. subsidised water treatment), and primarily comprising direct supplementary measures (e.g. provision of water sampling kits) to alleviate well maintenance costs. *Pro bono* incentives (e.g. free well testing) were reported in 10% ($n = 4$) of cases. With respect to intervention stakeholders (see Section 2.3), government bodies were the most frequently referenced coordinator type (48%, $n = 19$), followed by educational/research (45%, $n = 18$) and non-profit (38%, $n = 15$). Community actors (i.e. volunteer groups involved in interventions downstream) were noted in 20% ($n = 8$) of interventions, all of which were implemented in developing countries.

3.2. Development status

A total of 15 identified interventions (38%) originated from developed (high development) countries and 25 (63%) from developing (low/medium development) countries (Table 4). More than three quarters of information campaigns (77%, $n = 20$) took place in developing countries, while all workshops ($n = 4$) were undertaken in developed countries. A difference approaching statistical significance was found between primary (i.e. overarching) intervention type ($\chi^2 = 11.006$, $p = 0.051$) and development status (Table 6); source installation, source remediation and source treatment-based initiatives were exclusive to developing countries while all interventions entailing workshops as a strategy (primary or otherwise) were documented in developed countries. Over three quarters ($n = 19$) of interventions in developing countries comprised >1 intervention type (i.e. multimodal strategies) compared to 27% ($n = 4$) in developed countries ($\chi^2 = 9.337$, $p = 0.002$). Intervention reach was also significantly associated with development category for large-scale interventions ($\chi^2 = 6.009$, $p = 0.014$), with 47% ($n = 7$) of interventions undertaken at this scale in developed countries compared to 12% ($n = 3$) in developing countries.

Convenience mechanisms were encountered in all interventions in developing countries ($\chi^2 = 14.141$, $p < 0.001$), with print mechanisms more prevalent in developed countries (87%, $n = 13$) ($\chi^2 = 8.095$, $p = 0.004$). Presence of an incentive was also significantly associated with development status ($\chi^2 = 6.327$, $p = 0.012$); almost all interventions in developing countries (96%, $n = 24$) contained ≥ 1 incentive compared to 67% ($n = 10$) in developed countries. In terms of coordinator type, presence of a non-profit body ($\chi^2 = 11.111$, $p = 0.001$) was significantly associated with development status. Non-profit bodies had a coordinating role in 60% ($n = 15$)

Intervention differentiators (as defined by study authors):

a – high intensity well testing promotion, b – low intensity well testing promotion, c – pilot intervention, d – full intervention, e – households encouraged to seek water from wells below national arsenic standard, f – households receive additional information relating to arsenic safety and encouraged to seek water from wells with lower levels of arsenic (irrespective of national standard), g – performed by community members, h – performed by representatives from outside communities, i – household education, j – household education and local media campaign, k – mitigation village, l – comparison village I, m – comparison village II

of interventions in developing countries but were noted for only one intervention undertaken in a developed country.

3.3. Intervention evaluation and efficacy

Behavioural outcomes were measured in 93% (n = 37) and knowledge outcomes in 60% (n = 24) of interventions (Table 5). Outcomes were measured via knowledge, attitudes and/or practices (KAP) surveying in 39 out of 40 intervention evaluations, with the remaining study (Paul et al., 2015) measuring behaviour change via number of well water samples submitted for testing. The most frequent behavioural outcome type was use of a safe water source (n = 14), e.g. a newly abstracted well, while risk awareness (n = 17) was the most common type of knowledge outcome.

Discounting outlier values (resulting in truncated mean values), the mean efficacy of all interventions was 45% (SD = 26.46), with

interventions in developing countries exhibiting a mean of 44% (SD = 28.30) and developed countries a mean of 47% (SD = 24.02) (Table 7).

3.4. Behavioural outcomes

The mean level of behavioural change reported in developed countries was 46% (SD = 22.49) compared to 56% (SD = 41.70) in developing regions. Based on primary intervention type, highest mean behavioural outcomes were recorded for source remediation (135%, n = 1), followed by safe source installation (72%, SD = 48.85) and workshops (65%, SD = 16.38). In terms of reach, mean behavioural outcomes were highest for small-scale interventions (64%, SD = 14.18), with large- and medium-reach interventions performing at 55% (SD = 32.79) and 43% (SD = 35.60), respectively.

Mean behavioural outcomes displayed a significant associated with involvement of educational/research coordinators in inter-

ventions ($F = 5.712$, $p = 0.023$). Interventions under sole or co-supervision of educational/research coordinators attained a mean behavioural increase of 66% ($SD = 34.29$) compared to 38% ($SD = 38.67$) for those comprising other coordinators. Behavioural outcomes were also significantly associated with involvement of an educational/research coordinator when controlling for study design (i.e. presence of baseline or *pre-intervention* data) and development status (Table 8). Interventions involving a non-profit organisation in implementation accomplished a mean behavioural outcome of 63% ($SD = 28.08$) while those comprising other coordinator types attained a mean behavioural outcome of 46% ($SD = 40.044$). Interventions involving a government coordinator accomplished a mean behavioural increase of 48% ($SD = 40.68$) in contrast to 57% ($SD = 32.09$) for interventions implemented by different coordinator types (Table 9).

Interventions employing ≥1 incentive-based measure (e.g. free well testing) accomplished a mean behavioural change of 54% ($SD = 37.75$) compared to 45% ($SD = 27.713$) for interventions foregoing incentives. With respect to intervention mechanisms (Figure 4), highest rates of behaviour were associated with presence of

electronic-based mechanisms (64%, $SD = 40.35$), followed by interpersonal (58%, $SD = 39.38$), convenience (53%, $SD = 37.93$) and print (51%, $SD = 27.59$) (Fig 5).

4. Knowledge outcomes

The mean knowledge outcome reported in developed countries was 48% ($SD = 37.55$) compared to 47% ($SD = 25.75$) in developing regions. Highest mean knowledge outcomes were attained by interventions comprising workshops (82%, $SD = 14.85$), significantly outperforming information campaigns (41%, $SD = 28.23$) and well testing services (47%, $SD = 28.88$). Large-scale interventions were associated with the greatest increase in knowledge (61%, $SD = 35.15$), followed by medium (56%, $SD = 23.08$) and small-scale initiatives (36%, $SD = 29.73$).

A mean knowledge outcome of 53% ($SD = 26.93$) was attained by interventions under supervision of an educational/research coordinator compared to 44% ($SD = 32.81$) for those involving other coordinator types. Interventions under supervision of a governmental organisation in accomplished a mean knowledge outcome

of 43% ($SD = 36.14$) while those comprising other coordinator types attained a mean behavioural outcome of 52% ($SD = 21.14$).

No difference in mean knowledge attainment was identified based on presence of absence of incentives, with a mean performance of 48% recorded interventions with and without incentives ($SD = 28.66$; $SD = 36.78$). Interpersonal mechanisms comprised the most successful engagement channel in knowledge attainment (54%, $SD = 27.43$), followed by electronic (53%, $SD = 37.30$), convenience (51%, $SD = 25.11$) and print based mechanisms. (41%, $SD = 29.59$).

5. Discussion

The current study is the first to quantify the efficacy of private well interventions for improving awareness and protective behaviours among private groundwater users. Interventions implemented globally during the period 1990–2018 were identified via a systematised review and their results pooled with analyses delineated to control for intervention characteristics and country development status (Schardt et al., 2007). Overall, findings indicated that instructor-led, practical interventions allied with both large- and local-scale awareness-raising campaigns may represent an optimum approach for future private well risk prevention initiatives. Further to identifying the current success (and predictors thereof) of pertinent risk mitigation strategies, this study high-

lights a series of unique characterisations and limitations in both intervention reporting and scope which also merit reflection.

5.1. Global distribution of interventions

The continents of North America, Asia and Africa collectively constitute approximately 80–90% of the estimated 2.2 billion groundwater users worldwide (Murphy et al., 2017). However, the interventions identified in this review were largely concentrated within the Indian subcontinent and the North-eastern United States, thus accounting for a relatively limited proportion of global private groundwater users. The absence of studies evaluating interventions in Oceania, Europe and South America, may be due to growing urbanisation, lower private groundwater reliance, absence of research-led interventions, publication bias, and warrant future research attention. In some instances, the absence of interventions promoting private well maintenance behaviours and risk awareness may be attributable to government capacity or lack of subsequent “follow through”. Bundschuh & Garcia (2008) and McClintock et al. (2012) note a paucity of data regarding current groundwater arsenic burdens and an absence of remedial interventions in Latin American countries; this in spite of recent estimates placing the number of Latin American populations exposed to chronic concentrations of arsenic at 4.5 million. Significantly, Bundschuh & Garcia (2008) reference a small number of

field studies piloting arsenic removal technologies. Although a number of similar studies were identified in the current literature review (e.g. [Cheng et al., 2004](#); [Berg et al., 2006](#)), such interventions were evaluated based on contaminant removal efficiency and human health improvements as opposed to behaviour and knowledge attainment. As noted by Jones-Hughes *et al.* (2013), interventions premised on installation of contaminant removal technologies may not lead to sufficient, long-term health outcomes in and of themselves and must be better tailored towards (or reported with respect to) behaviour and knowledge acquisition.

5.2. Reported contaminants

Notably, the majority of included studies evaluated interventions associated with reducing geogenic (chemical) contaminants in specific “hotspots.” The most represented countries in the current review, Bangladesh and the United States, are the subject of historically intensive groundwater arsenic mitigation programmes ([Anderson et al., 2015](#); [Henry & Suk, 2018](#)). Conversely, and of potential concern, prevention of microbial contamination was encountered within just one identified intervention (Lule *et al.*, 2005). This suggests a global lack of appreciation of the scale and severity of groundwater contamination by enteric pathogens and pervasive deficit of remedial interventions ([Howard et al., 2006](#); [Bradford & Harvey, 2017](#)). While the global groundwater arsenic burden is considerable ([Ravenscroft et al., 2009](#)), 35–59 million annual cases of enteric infection are attributable to microbial groundwater contamination ([Murphy et al., 2017](#)). As information

pertaining to the rates and consequent risks of regional microbial groundwater contamination become more widespread, a concurrent increase in correspondent interventions is required to address increasing waste production and climate-related challenges to groundwater quality. Although a number of studies external to this review have indeed evaluated interventions implemented in areas characterised by microbial groundwater contamination ([Odagiri et al., 2016](#)), outcomes were premised on improvements in human health and/or contaminant reduction as opposed to behaviour and knowledge attainment.

5.3. Intervention types

As is common in awareness raising interventions intended to reach relatively large audiences ([Atkin & Rice, 2012](#)), information campaigns were the most frequently reported intervention type in both development contexts. Interventions in developing countries were typically associated with conventional water and sanitation initiatives often observed in low/medium-development regions such as water testing services and provision of water treatment mechanisms ([Mosler, 2012](#)). A greater number of workshop-based initiatives were noted in developed countries in the form of network-based forms of rural outreach delivered by state universities in partnership with federal, state and local governments ([Franz, 2014](#)). However, interventions in developed countries were generally less predicated on direct engagement with and actions on behalf of households, with water testing services and provision of treatment mechanisms less frequent. Additionally, interventions

in developed countries adopted convenience mechanisms and incentives significantly more often than developing countries. These findings indicate that private well interventions in developed countries may assume an appreciably greater capacity for private well stewardship and maintenance actions among target audiences. Conversely, opportunities for interpersonal engagement in developing nations may be more frequent due to less secure land title and stigma surrounding private well maintenance (Boyle et al., 2010). It is thus advisable for intervention coordinators in developed countries to engender trust and cooperation with communities from the outset and give greater consideration to the efficacy of convenience, incentive-based approaches (Re, 2015; Morris et al., 2016).

5.4. Intervention stakeholders

While the type of documented stakeholders within interventions was not strictly geographically orientated, participation of non-profit bodies was significantly related to development status. Moreover, downstream involvement of community actors (e.g. assistance in information dissemination) was limited to eight interventions, all of which occurred in developing countries. The absence of documented community actors in developed countries may be seen as noteworthy, given that more than half of interventions in developed countries were implemented at the regional- or local scale; interventions undertaken on a sub-national scale may be better placed to utilise community channels to engage private well users on a more concerted, face-to-face basis (Morris et al., 2016). Furthermore, community and civil society organisations have been repeatedly recognised as an important means of private well user outreach in these regions (Morris et al., 2016; Henry & Suk, 2018). Significantly, the most frequent coordinator type documented in developed countries was a government body, suggesting that private groundwater interventions in developed countries are generally top-down in nature and may be insensitive to place-specific circumstances. Educational/research bodies were the only consistent coordinator type active in both development categories, suggesting a higher comparable level of expertise and potentially larger funding streams relative to other coordinators with respect to private well user outreach. As educational/research body coordinators were associated with higher behavioural efficacy, they may be best placed to facilitate greater engagement and participation with local, community-based organisations.

5.5. Intervention outcomes

Although interventions undertaken in developed countries registered a slightly higher overall success rate than developing coun-

Figure 4. Forest plot demonstrating levels of behavioural attainment (%) with corresponding intervention mechanisms.

Figure 5. Forest plot demonstrating levels of knowledge attainment (%) with corresponding intervention mechanisms.

tries (47% vs. 44%), mean behavioural outcome was analogous across development type (47% vs. 48%). This may be partly ascribed to higher baseline rates of well maintenance (potentially related to higher mean levels of education and income) and/or a lack of assistance relative to interventions in developing countries (Flanagan et al., 2015). This low rate of behaviour change is somewhat similar to previous figures relating to private well user maintenance actions measured in KAP surveys in developed countries, which noted acceptable well maintenance behaviours in approximately 30% of surveyed well users (Kreutzweiser et al., 2011; Malecki et al., 2017). Highest rates of behaviour change were associated with safe source installation (mean improvement = 135%), although workshops (mean improvement = 65%) were the most successful primary intervention type in this regard that did not automatically stipulate direct assistance such as well installation or maintenance measures on behalf of householders. The greater

success rate in promoting behaviour change compared to information campaigns and well testing services indicates the high productivity of first-hand, interactive interventions in stimulating appropriate private well maintenance. Notwithstanding the validity of these interventions, it is vital that circumstantial and audience-related factors are acknowledged in intervention design as standardised approaches may disregard social, value-based and experiential factors such as frequent correlates with health and water maintenance behaviours (Figuerola & Kincaid, 2010; Moore & Boldero, 2017). As participation of educational/research coordinators was also shown to engender significantly higher rates of behaviour change (in both general terms and controlling for development status and study design), their enhanced involvement in subsequent interventions may bear consideration at government level. Involvement of intervention coordinators combining pedagogical and technical expertise may increase the

likelihood of desired behavioural adaption on the part of well owners, validating calls for greater involvement of educational experts in hydrogeological interventions (Re, 2015; Hynds et al., 2018).

The lower increase in mean knowledge (47%) attained in developing countries relative to behaviour may be attributable to lower audience literacy rates and a less immediate requirement for information assimilation by virtue of intervention type (e.g. safe source installation undertaken by intervention coordinators/actors) (Jones et al., 2013). Locally adopted interventions attained the highest improvement in behaviour while large-scale interventions attained the highest knowledge increase with respect to audience reach. Highest knowledge outcomes were attained by workshops, further underscoring the efficacy of workshops relative to other intervention types. Two cooperative extension programmes predicated on interpersonal workshops and convenience-based measures (e.g. provision of water sample bottle, well test result interpretation) registered notably high behaviour outcomes (Benham et al., 2016; Clemens et al., 2007). However, as was also observed for behaviour, type of intervention mechanism demonstrated no significant relationship with knowledge outcome. This may denote that efficacy of intervention activities is premised on the quality as opposed to type of engagement material, as noted by Figueroa & Kincaid (2010) in the context of developing nations. Notably, the majority of knowledge measures were based on awareness of contamination risk as opposed to knowledge of private well maintenance; attainment of ≥ 1 form of supply maintenance knowledge was measured in only two interventions, once more evincing a lack of focus on well user self-efficacy (Hynds et al., 2018).

The viability of locally scaled interventions in addressing complex human health scenarios (e.g. contaminated domestic water supplies) is repeatedly cited in the health outreach literature and further reinforces the efficacy of locally tailored interventions in promoting enhanced private groundwater quality, stewardship and user health (Craig et al., 2008; Figueroa & Kincaid, 2010). Conversely, supra-regional (i.e. state/national) interventions such as public communication campaigns may also be required to raise initial awareness or generate discourse; large-scale campaigns performed markedly better than medium-scale interventions. The efficacy of source remediation and safe source installation campaigns and workshops suggests that a combination of household or community-based interventions with interpersonal, practical interventions represent optimal intervention strategies. Such interventions are inherently more effective at the local level but may transcend individual town or village setting if replicated consistently in accordance with an overarching strategy and audience analysis (Milat et al., 2015). On this basis, it is recommended that groundwater outreach practitioners prioritise design and employment of both locally focused, interdisciplinary rural private well interventions and large-scale awareness raising strategies, allied with educational initiatives and tailored awareness-raising campaigns. Concerted and sustained collaboration among stakeholders comprising hydrogeologists, behavioural scientists and community/voluntary agencies will be necessary to encourage development of feasible, replicable intervention frameworks and, by extension, prevalent rural private groundwater stewardship.

5.6. Study limitations

The current review strictly adhered to a systematised review framework and is thus characterised by a number of inherent limitations. As with all scientific reviews, the potential presence of publication bias may impact on the type and location of studies published and reported outcomes. Interventions were largely concentrated within two continental sub-regions, thus potentially limiting the transferability of intervention findings on a global scale. It is further anticipated that a number of interventions may have

been undertaken in areas encompassing peri-urban municipalities, in spite of specification of broad rurality. In light of these factors, it is urged that review findings, notwithstanding their potential value, be utilised cautiously.

6. Conclusion

Contamination of potable groundwater poses a significant global health threat – one most acutely experienced among rural private owners due to infrequent and inconsistent supply regulation, localised natural and anthropogenic hazards and increased susceptibility to contamination pathways shaped by modern peri-urban/rural development and climate change dynamics. The pervasive absence of “top-down” supply management via regulation and consequent burden of responsibility placed on well owners themselves prescribes an evidence-based, communicative approach to groundwater risk prevention. The lack of reported interventions in Europe, Australia and South America underscores the potential significance of “place-based” factors such as social geography, policy and institutional capacity/research priorities in determining the occurrence and evaluation of private well interventions. While different geographical regions may require different approaches, the absence of community and voluntary sector coordinators in interventions within developed countries set against requests for their increased involvement therein points to a disconnect that requires attention in intervention design/strategies. This disconnect is also manifest in the distinct lack of private well interventions pertaining to microbial contamination, which warrants increased consideration by governmental and hydrogeological communities alike.

Differences in intervention type (and performance/outcome) with regard to development status may be anticipated given the socio-economic range of target audiences and consequently varying intervention priorities. However, while there is inherent value in examining development categories separately, comparisons may be drawn. Interventions undertaken in developing countries are distinguished by a stronger local focus and a more interpersonal, incentivised-approach. Given the higher overall behaviour rate exhibited among developing country interventions and the observed efficacy of locally-implemented initiatives, an informed adoption of comparable measures in developed countries may result in comparable outcomes. However, higher knowledge rate increases associated with large-scale interventions may indicate the value of a wide geographical reach in generating greater collective discussion and by extension awareness. While the documented efficacy of education/research coordinator-led interventions and workshops reinforces the validity of instructor-led interventions, it is nevertheless vital that they are tailored accordingly based on circumstantial factors and audience analysis.

Conflict of Interest

All authors confirm that no actual or potential conflict of interest exists including any financial, personal or other relationships with other people or organizations within three years of beginning the submitted work that could inappropriately influence, or be perceived to influence, this work.
