ABSTRACT

Functional hybrid sol-gel coatings have been developed for numerous applications with a wide range of wettabilities. This study proposes to investigate the relationship between the structure and the wetting properties of a zirconium modified silicate hybrid sol-gel coating. The structures of the coatings were altered by varying the content of zirconium, and the curing process, while keeping the sol-gel preparation conditions identical. The structure of the materials was characterized by FTIR, ²⁹Si NMR and SEM. The thermal properties and the wettability are identified by DSC and contact angle measurements, respectively.

By corroborating the structural and wettability analyses, it is shown that the transition metal minimizes the thermally-assisted condensation of the silicate network and enables to stabilize the wetting properties at higher hydrophilic values. This article highlights that the wettability of hybrid sol-gel coatings can be controlled by both the curing process and transition metal content.

1. Introduction

Control of coatings wettability is of great interest for a wide range of applications; including sensors for medical and environmental monitoring, protective coatings for transportation and construction industries among others. One of the key issues with the development of highly sensitive sensor devices is the functionalization of sensing surfaces with recognition probes that enable specific binding with biological or chemical analytes, thus requiring sensing surfaces with controlled wettability [1]. Microfluidics are widely used in medical and environmental monitoring devices and their fluidic efficiency depends on their surface energy [2]. Protective coatings for anticorrosion, antifouling or antibacterial purposes often need low surface energies to minimize interactions between the protected surface and contaminant fluids [3]. High surface energy surfaces are essential for adhesion of organic coatings to enable the formation of homogenous and highly adherent coatings [4].

Over the past three decades, hybrid sol-gel materials have been widely investigated for the fabrication of functional coatings [5]. The dual organic and inorganic character of the precursors coupled to the liquid nature of the sol-gel process have been particularly attractive to the preparation of newly hierarchically structured materials with wettability ranging from (super)hydrophobic [6] to (super)hydrophilic [7,8]. However, to our knowledge, no research has precisely focused on

the influence of the curing and structure of the hybrid sol-gel material on the wettability of hybrid organic-inorganic sol-gel coatings. This study is aimed at providing initial responses to these fundamental questions by studying an established hybrid sol-gel material prepared from the combination of a silicate and zirconium hybrid precursors previously reported on by us [9]. While previous studies completed by us focused on the structure of the hybrid sol-gel coatings towards anticorrosion applications, this study centres on the effect of the curing on the structure and wettability of hybrid sol-gel coatings. To better understand the effect of the structure on the wetting properties of the coatings, the relative content of the silicon and zirconium precursors was altered while keeping the sol-gel synthesis and coatings fabrication conditions identical. The properties of the hybrid sol-gel materials were characterized employing Fourier transform infrared spectroscopy (FT-IR), silicon nuclear resonance spectroscopy (²⁹Si NMR) and scanning electron microscopy (SEM). The wettability was identified by contact angle measurements. The thermal properties were characterized by differential scanning calorimetry (DSC).

2. Experimental section

2.1. Sol gel synthesis

Five hybrid sol-gel materials were prepared from the combination of

Table 1
Materials formulation.

Materials	Theoretical hydrolysis degree (vs. alkoxide groups)	MAPTMS:ZPO:MAAH
A	50%	99:1:1
B	50%	95:5:5
C	50%	90:10:10
D	50%	80:20:20
E	50%	70:30:30

two hybrid precursors in different relative ratios (Table 1): (1) an organically modified silicate precursor, 3-(trimethoxysilyl)propyl methacrylate (MAPTMS, Assay 99% in methanol) and a zirconium complex, prepared from the chelation of zirconium n-propoxide (ZPO, Assay 70% in 2-propanol) with methacrylic acid (MAAH, Assay > 98%). The sol-gel synthesis necessitates a three-step process to enable the formation of a fully stable nano-hybrid system where zirconium species are homogeneously distributed within the hybrid silicate matrix, as fully described in our previous study [9].

2.2. Fabrication of the sol-gel coatings

The five prepared sols were filtered using a 0.45 µm nylon syringe filter and deposited onto glass substrates by spin coating at 1000 rpm. The glass substrates were cleaned with isopropanol prior to deposition. From each sol, five coatings were prepared and each one underwent a different curing temperature (100, 120, 130, 140 and 150 °C) for a duration of 1 h, resulting in a set of 25 samples. The process was repeated five times for reproducibility testing.

2.3. Contact angle measurements

Water contact angles (CA) were measured using the static sessile drop method on the hybrid sol-gel coatings. The measurements were taken using deionized water under ambient conditions using an electronic syringe. The CA measurements were recorded using a contact angle goniometer-FTA200 First Ten Angstroms. Uniform droplets of 4.1 µl of deionized water were dropped onto the surface of the coatings and allowed to stabilize for 10 s before digital images of the droplets were recorded. For statistical analyses, five coatings for each material were prepared with six measurements taken for each coating, leading to 30 values. The contact angle values were determined from the average of the 30 measurements and the uncertainty values determined from the minimum and maximum values of these 30 measurements. The images were then analysed using FTA32 Video 2.0 software.

2.4. Fourier transform infrared spectroscopy (FT-IR)

FT-IR was employed to highlight the different vibrational modes of the chemical species within the sol-gel coatings, particularly to follow the evolution of the silicate network when the curing temperature and zirconium content are altered. The FT-IR spectra of all coatings were obtained using a Perkin Elmer GX instrument in the ATR mode within a 650–4000 cm⁻¹ spectral range.

2.5. Silicon nuclear magnetic spectroscopy (²⁹Si NMR)

²⁹Si-NMR experiments were carried out for the sols 24 h after their synthesis. The main information of interest was the evolution of the condensation degree of the silicon atoms as a function of zirconium concentration. The experiments were run employing a 400 MHz Bruker spectrometer equipped with an INEP pulse sequence. The acquisition conditions are as follows: frequency 46.69 MHz, spectral width 500 ppm, pulse $\pi/3$ (8 µs), recycle delay 4 s, number of scans 80 and the free induction delay (FID) fixed at 10 Hz line broadening. Deuterated

dimethylsulfoxide (DMSO) was used as a lock solvent and tetramethylsilane (TMS) - as a chemical shift reference. For the statistical analyses of the content of the T species, each material was prepared three times and NMR spectra recorded three times, leading to nine measurements per material. The value of the T species was determined by the average of the obtained nine measurements and the uncertainty values defined from the minimum and maximum values of the nine measurements.

2.6. Differential scanning calorimetry (DSC)

DSC was employed to look at the thermal stability and reactivity of the sols over the temperature range of 25–300 °C. The measurements were carried out using a Shimadzu DSC QC instrument under an air atmosphere and a heating rate of 5 °C/min.

2.7. Scanning electron microscopy (SEM)

SEM experiments were performed on the cross-section of the coatings to identify their thickness, homogeneity and adhesion on the glass substrate.

The SEM images were recorded employing a Hitachi SU-70 SEM with electron energy of 2–10 keV. Prior to analysis, the samples were sputter coated with a palladium layer of approximately 6 nm in thickness using a Cressington 208HR sputter coater.

3. Results and discussion

3.1. Contact angle measurements

The contact angle (CA) measurement of all materials were performed and the average contact angles plotted as a function of temperature are shown in Fig. 1. At 100 °C, materials containing 1 to 20% ZPO exhibit a CA close to 67°, whereas the material containing 30% ZPO has a slightly higher CA value of 71°. As the temperature increases to a 120 °C it can be seen that the opposite tendency is observed with samples containing a high content of ZPO exhibiting lower CA values than those with a lower ZPO content. Interestingly, except for material A, all other materials show a stagnation of their CA value from a curing temperature of 130 °C. Unlike the other materials, material A shows an increase of the CA from 130 to 150 °C. These observations clearly signify that the zirconium content plays a role in the surface properties of the materials. The hypothesis to explain this behaviour can be related to the formation of hydrophilic species at temperatures up to 130 °C with a partial conversion of the hydrophilic species into hydrophobic groups. However, this variation can only be possible if the morphology of the materials is dramatically different from low to high ZPO concentrations, therefore favouring the conversion of hydrophilic species to hydrophobic species at low ZPO concentrations. In other words, this

Fig. 1. CA measurements vs temperature for all materials.

Fig. 2. FT-IR spectra of materials A–E in the range of 650–4000 cm^{-1} .

phenomenon would be possible if material A exhibits a higher porosity than other materials, therefore having the ability to be hydrophilized at temperatures lower than 130 °C and hydrophobized at higher temperatures. This would mean that the surface properties would be governed by a competition between a hydrophilization process at low temperatures and a hydrophobization process taking place at higher temperatures, likely due to the conversion of hydroxyl groups into oxide groups. In order to confirm or disconfirm this hypothesis, FT-IR analyses of the evolution of the inorganic groups are required.

3.2. FT-IR

The recorded FT-IR spectra for all materials were found to exhibit similar chemical vibrations, as shown in Fig. 2 (samples cured at 100 °C). This is due to the formation of the same chemical groups because of a uniform preparation process, the only difference being the MAPTMS/ZPO ratio. To identify the effects of the curing temperature and material formulations on the reactivity and condensation of the inorganic network, it is important to focus on the characteristic absorption bands of the inorganic backbone of the materials. For this reason, the absorption bands in the range 800–1250 cm^{-1} were investigated, as shown in Fig. 3. In the previous study [9], it was found that, for a curing temperature of 120 °C, the ZPO content significantly affects the absorption in the 800–1250 cm^{-1} range, but here the effect of the curing temperature is investigated in the domain of temperatures usually required for fully stabilizing hybrid sol-gel coatings, from 100 to 150 °C. The absorption bands were attributed according to the results of previous studies [10–15]. For material A, it can be observed that the Si–O–Si symmetric stretching band located at 815 cm^{-1} and the Si–O–C symmetric stretching bands located at 1170 and 1200 cm^{-1} decrease when the curing temperature increases. In parallel, the broad band located in the range 1000–1100 cm^{-1} and related to the asymmetric stretching of the Si–O–Si bonds is seen to shrink from the high energy vibrations as the curing temperature increases. Actually, this band is composed itself by the superimposition of five sub-bands located at 1010, 1030, 1055, 1070 and 1090 cm^{-1} . According to Lerot and Low [16], the band located at 1090 cm^{-1} is attributed to siloxane units located at the interface between tetrahedral and octahedral units, whereas the lower energy bands would relate to siloxane units at the interface between tetrahedral units. From this reference, one can suppose that in our system, in this spectral region, the high-energy vibrations would represent the siloxane bonds with a more structured network whereas the lower ones would be related to a more disordered network. Therefore, the decrease of the intensities of the bands with higher energy indicates the formation of a network with a lower connectivity, probably with a higher porous morphology. This hypothesis is supported by the intensity decrease of the symmetric stretching of the Si–O–Zr bond located at 940 cm^{-1} . Finally, although the intensity of the band related to the symmetric vibration of the Si–OH group located

at 890 cm^{-1} is seen to decrease, its relative intensity against the Si–O–Si groups (815 and 1000–1150 cm^{-1}) is found to be the highest for the sample cured at 130 °C. This supports the CA measurements where the sample cured at 130 °C was found to be the most hydrophilic sample for material A. In summary, for material A, the increase of the curing temperature provokes the formation of hydrophilic silanol groups at up to 130 °C. The higher curing temperatures tend to form hydrophobic siloxane groups with increasing amorphous character of the inorganic network.

For materials B to E, the bands related to the symmetric siloxane (815 cm^{-1}) and residual alkoxy silane (1175 cm^{-1}) groups are seen to decrease as the curing temperature increases. The relative intensity of the silanol (840 cm^{-1}) groups against the symmetric siloxane stretching increases as the concentration of the zirconium precursor increases, suggesting that the zirconium atom favours the formation of hydrophilic Si–OH groups. The shrinkage of the asymmetric siloxane vibrations bands (1000–1150 cm^{-1}), which was identified for material A, is not observed for materials B to D and the opposite effect is observed for material E. The progressive increase of the zirconium content minimizes the decrease of the Si–O–Zr band located at 940 cm^{-1} , suggesting the formation of more stable structures. Therefore, one can conclude that the zirconium precursor favours the formation of highly condensed silicate species, resulting in a more condensed network. Finally, these results indicate that the incorporation of the transition metal favours the formation of denser materials, thus limiting the further condensation process observed in material A, and the subsequent contact angle increase. However, to better identify the effect of the zirconium incorporation on the morphology of the silicate network and its subsequent consequences on the wetting capabilities of the coatings, we propose to perform ^{29}Si NMR analyses of the materials investigated here. Importantly, this would enable us to confirm or disconfirm the competition between the hydroxylation and condensation processes discussed in this section.

3.3. ^{29}Si NMR

The ^{29}Si NMR spectra were recorded for all materials 24 h after fabrication and they are shown in Fig. 4. The spectrum of the precursor MAPTMS was also recorded and is represented in Fig. 5. The presence of a single sharp peak at –42.6 ppm demonstrates the absence of hydrolysed or condensed species and its high purity. The presence of the different chemical shifts in the T_0 , T_1 , T_2 and T_3 regions of the spectra correspond to the different degrees of condensation of the silicon atoms in MAPTMS and it was previously reported [9]. Firstly, it can be noted that no T_0 species are observed for any material, suggesting that all silicon atoms have formed at least one siloxane bond. However, this does not mean that all alkoxy group have reacted, as each silicon atom within MAPTMS contains 3 reactive alkoxy groups. To better appreciate the evolution of the different T species for each material, the different chemical shifts have been integrated and their relative proportions are plotted in Fig. 6. T_1 species are present in all materials A–E at ratios of 32.2, 4.8, 2.7, 3.5 and 13.3%, respectively. T_2 species are present at a ratio of 50, 50.3, 45.2, 42.4, and 44.2%, respectively. The most condensed species T_3 is present in concentrations of 17.1, 44.8, 52, 54, and 42.4%, respectively. The increase of the T_3 species at the expense of both the T_2 and T_1 species suggests that the materials are forming more condensed networks with increasing zirconium concentrations up to 20%. For material E, with a ZPO concentration of 30%, there is a dramatic increase in the concentration of T_1 species with a decrease in the T_3 species.

In summary, the ^{29}Si NMR analyses suggests the zirconium precursor favours the formation of a more condensed silicate species at concentrations up to 20%. At a concentration of 30%, the lower condensed T_1 silicate species are formed minimizing further condensation probably due to the steric hindrance caused by the large size of the zirconium atom. Importantly, these results confirm that the silicate

Fig. 3. FT-IR spectra of materials A–E in the range of 800–1250 cm^{-1} .

network is less sensitive to condensation reactions as the zirconium content increases and to subsequent contact angle increase, as demonstrated above by the CA and FT-IR analyses.

3.4. Thermal analysis

The DSC measurements were performed on all the liquid sol-gel materials to determine their thermal behaviour and to identify the optimum working temperature of the sol-gel material. The thermal behaviour of materials A–E are given in Fig. 7. There are three different areas of thermal behaviour that can be observed, namely, between 25 and 70 °C, 100 and 170 °C and above 170 °C. The large broad endothermic band between 25 and 70 °C is due to the evaporation of free volatile solvents within the hybrid network formed during the sol-gel synthesis and contained in the precursors. The endothermic band shifts to higher temperatures with increasing zirconium content; this may be due to a higher degree of entrapped solvents in the sol-gel network. Similar behaviour has been reported for Sn doped ZrO_2 samples which were prepared by sol-gel methods [17]. The exothermic band between 160 and 190 °C is due to the glass transition phase (T_g) or the full solidification point of the sol-gel materials. It can be noted that the T_g for materials B to E can be seen at 194, 194, 185 and 199 °C, respectively.

Material A, exhibits two exothermic bands in the region of 171 and 192 °C, which may be due to the occurrence of two different phases within the material due to the low content of ZPO, as previously observed in similar materials [9]. Apart from materials C and D, an additional exothermic band located above 200 °C is present for the other materials, translating structural heterogeneity, probably due to the presence of hybrid nanoparticle populations with different structures, thus with different thermal behaviors. The most plausible explanation to the likely heterogeneity can be explained by the capability of the silicate network to host the zirconium complex in a homogeneous manner within its backbone. At low zirconium concentrations (materials A and B), the sol-gel network may be primarily composed of silicate species with some local inclusions of zirconium species. At the highest zirconium content (material E), the silicate network may not be able to host the whole content of zirconium species, thus leading to some rich zirconium nanoparticles populations. According to this explanation, the integration of the zirconium complex in the silicate network is optimum in materials C and D. However, to clarify this question further fine structural characterizations at the different curing temperatures employing XRD, EXAFS, XANES or neutron scattering are needed, which we expect to address in a future study.

Fig. 4. ^{29}Si NMR spectra of all materials.

3.5. SEM analysis

The SEM images of cross-sectioned samples were recorded to identify the coating homogeneity and thicknesses, as well as adhesion on the glass substrate for all materials. All samples show homogenous coatings with thicknesses in the range of $4.8\text{--}6\text{ }\mu\text{m}$ ($\pm 0.5\text{ }\mu\text{m}$), as seen

in Fig. 8. Although the sample preparation involved mechanical cleaving of the substrate in order to enable cross-section analysis on a sharp interface, no delamination of the coatings from the glass substrate was observed, demonstrating a strong adhesion of the sol-gel materials with the glass substrate. As the glass substrate surface contains silanol groups, it is likely that they will undergo inorganic condensation with

Fig. 5. ^{29}Si NMR spectra of pure MAPTMS precursor.

Fig. 6. Evolution of T₁, T₂ and T₃ species for all materials.

Fig. 7. DSC spectra of all materials.

the residual uncondensed silanol and alkoxy silane groups of the sols to form strong siloxane bonds, thus explaining the strong adhesion of the hybrid sol-gel coating onto the substrate. Apart from the stripes observed on the cross-section, which are due to the propagation of the cleaving defects of the glass substrate, the coating is found to be smooth and uniformly distributed on the substrate, suggesting a highly homogeneous material.

4. Conclusion

The objective of this work was to investigate the relationships existing between the structure, the curing temperature and the wetting properties of a zirconium modified organosilane hybrid sol-gel material. A series of five hybrid materials were prepared from the combination of a silicon and zirconium hybrid sol-gel reactive at different ratios. The materials were structurally and thermally analysed by FT-IR, ²⁹Si NMR, SEM and DSC methods and the wetting properties clarified by CA measurements. The FT-IR analysis showed that the curing temperature provokes the condensation of the silicate network at the expense of the Si–O–Zr and Si–OH groups. However, this phenomenon decreases as the zirconium content increases, suggesting the zirconium precursor minimizes the progression of the silicate network probably by the formation of a rigid network in the liquid phase. Indeed, ²⁹Si NMR characterizations have supported this hypothesis by showing that highly condensed silicate species are formed in the liquid phase when the content of zirconium increases. From the cross-section SEM observation, the prepared coatings are found to be uniformly deposited onto the glass substrate with thicknesses ranging from 4.8 to 6 μm (± 0.5 μm). The wettability analysis showed that all coatings exhibit a progressive decrease of their CA values up to 130 °C. At temperatures above 130 °C, the sample containing 1% zirconium content exhibits an increase of its CA value, while coatings containing a minimum of 5% of zirconium maintain a stable CA value. Therefore, when corroborating the structural and wettability analyses, it has become evident that the transition metal minimizes thermal condensation of the silicate network, thus enabling stabilization of the wetting properties at higher hydrophilic values.

To our knowledge, the control of the wettability of hybrid coatings by curing process and transition metal incorporation within a silicate network is a fundamentally new concept in the physico-chemistry of hybrid sol-gel materials, which would deserve to be further investigated on other structurally different materials and other curing methodologies.
