A refractive index (RI) sensor based on a novel fiber structure which consists of a singlemode-multimode-singlemode (SMS) fiber structure followed by a fiber Bragg grating (FBG) was demonstrated. The multimode fiber (MMF) in the SMS structure excites cladding modes within output singlemode fiber (SMF) and re-couple the reflected cladding Bragg wavelength to the input SMF core. By measuring the relative Bragg wavelength shift between core and cladding Bragg wavelengths, the RI can be determined. Experimentally we have achieved a maximum sensitivity of 7.33 nm/RIU (RI unit) at RI range from 1.324 to 1.439.

Both the SMF and MMF fibers in figure 1 have a step index profile. When the light injected from the input SMF into the MMF, multiple modes will be excited and will propagate within MMF. This is a promising technique, but imprinting of an LPG will add fabrication complexity and extra cost to the refractometer. Previous investigations show that a singlemode-multimode-singlemode (SMS) fiber structure can excite and couple multiple modes to a singlemode fiber (SMF) [10-14]. In this paper we propose to use an SMS followed by an FBG imprinted SMF (SMS+FBG) to measure SRI. Compared to [9], our proposed technique has advantages of simple configuration and easy fabrication. More importantly the spectral response of an SMS fiber structure can be easily adjusted by selecting different types and length of the MMF. The proposed SMS+FBG refractometer structure is shown in figure 1.

In figure 1, an SMF fiber is fusion spliced to an MMF and followed by a fusion splice to an FBG imprinted SMF.
light enters the SMF core while the remaining portion is coupled into the SMF cladding. In this case the output SMF can be considered as a three layer structure where the medium surrounding the fiber cladding is the 3rd layer of the fiber [15]. The coupling coefficients can be expressed as follows:

\[
c_n = \frac{\int E(r,z)\Phi_n(r)dr}{\int \Phi_n(r)\Phi_n(r)dr}
\]

where \(\Phi_n(r)\) is \(n^{th}\) mode within the output SMF (\(n=1\) represents the core mode and \(n>1\) represent cladding modes). Assuming the splice between the SMF and MMF is ideal, only \(LP_{0m}\) and \(LP_{0n}\) modes will be excited within the MMF and SMF respectively, due to the circular symmetry of the input field [13-14]. The calculated coupling coefficients for the first eleven modes to the output SMF are shown in figure 2.

Fig. 2 Calculated coupling coefficients to the output SMF for different modes in the SMS structure as a function of MMF length

In this simulation, the MMF has core and cladding diameters of 104 and 125 \(\mu m\) and refractive indices of 1.4446 and 1.4271 respectively. The SMF has a core and cladding diameters of 8.3 and 125 \(\mu m\) and refractive indices of 1.449 and 1.445 respectively and the SRI is 1.33. The wavelength used in the simulation is 1550 nm.

Figure 2 shows that at a particular wavelength, coupling coefficient \(c_n\) is determined by the MMF length. By properly selecting the MMF length, a relatively high \(c_n\) can be achieved for a particular cladding mode. When these modes arrive at the FBG, they will be reflected by the FBG and the reflected wavelength can be expressed by the following equation [9]:

\[
\lambda = 2n_{eff}(n)\Lambda
\]

where \(\Lambda\) is the Bragg grating period, \(n_{eff}(n)\) is the \(n^{th}\) effective RI of the output SMF (\(n=1\) represents the core mode and \(n>1\) represent cladding modes). As the SRI changes, the effective RI of the cladding modes will change but that of the core mode remains unchanged. Using a broadband source and monitoring the relative shift between the reflected wavelengths of selected cladding and core modes, the SRI can be determined.

Experiments based on the above structure were carried out. The single- and multimode fibers used in our experiment were SMF28 and AFS105/125Y respectively. The length of the MMF was 42.1 mm. The FBG was imprinted in an SMF28 which had a grating length of 50 mm and reflectivity of 50%. The distance between the end of the MMF section and beginning of the FBG was circa 5 mm.

The transmission spectrum of an SMS fiber structure is shown in figure 3(a). It can be seen that there is a transmission peak at a wavelength circa 1540 nm. The FBG used in our experiment has a core Bragg wavelength of 1545 nm. When the light, for example from a broadband source, is injected from the FBG end (right hand side in Fig. 3(b)), the reflective spectrum has only one peak wavelength at circa 1545 nm which is the core Bragg grating wavelength. However if the light is injected from the MMF end (left hand side in Fig. 3(c)) there are multiple reflected wavelength peaks. This is because multiple modes excited in the MMF section propagate in both the core and cladding of the output SMF in the region where FBG is imprinted and both the core and cladding modes are reflected by the FBG and re-coupled to the MMF. The re-coupled light is transmitted through the MMF again and coupled back to the core of the input SMF. In Fig. 3(c) \(\lambda_0\) is the core Bragg wavelength, \(\lambda_1\) and \(\lambda_2\) are cladding Bragg wavelengths corresponding to 3rd and 5th order cladding modes.

Experimental investigations were carried out by immersing the SMS+FBG structure into liquids with different RI values. The reflective spectral responses
corresponding to different SRI are shown in figure 4 for the reflected Bragg wavelengths of the core mode and two cladding modes.

Figure 4 shows that as the SRI increases, the core Bragg wavelength remains unchanged (Fig 4(a)), but the cladding Bragg wavelengths experience red shift. This is due to the fact that as the SRI increases, the effective RI of the core mode remains unchanged, while the effective RI of \( n^{th} \) cladding modes increases with an increase of the SRI, resulting in the corresponding increase for the cladding Bragg wavelength. The measured relative wavelength shifts between core and cladding Bragg wavelengths vs. SRI is shown in figure 5(a).

Figure 5 shows that as the RI increases from 1.324 to 1.439, there is 87 pm and 46 pm relative peak wavelength shift for \( \lambda_0 - \lambda_2 \) and \( \lambda_0 - \lambda_1 \) respectively. This result indicates that higher order cladding modes will have higher sensitivity to the change of SRI compared to lower order cladding modes. Figure 5(b) shows the simulated relative wavelength shift for 3rd and 5th order cladding modes vs. RI variations, which agrees well with the experimental results as shown in Fig. 5(a). In this simulation, the SMF fiber has the same parameters as above and the Bragg grating period \( \Lambda \) is 534 nm.

In conclusion we have proposed a novel RI sensor based on an SMS+FBG fiber structure. This structure utilizes MMF to excite cladding modes within an FBG imprinted SMF and re-couple reflected cladding Bragg wavelength to the input SMF core. By measuring the relative core-cladding Bragg wavelength shift, the RI can be determined. Experimentally we have achieved a maximum sensitivity of 7.33 nm/RIU (RI unit) in the RI range from 1.324 to 1.439. The sensitivity can also be enhanced by optimizing the parameters of the fiber used [16]. Finally it is important to point out that this work has more general applications, in that it is possible to use an SMS fiber structure instead of a LPG to couple cladding modes to a core mode.
